This is the latest of the Students' Aid Series of manuals, the previous issues of which have been reviewed from time to time in this column. It presents all the essential facts of histology in small compass and serves excellently both as an introduction to this subject for the young student and as a review book for the advanced student or the recent graduate preparing for examination for the degree or for a licence to practise. The matter is well arranged and the student is led on gradually from the simpler to the more complex tissues. The final chapter is on histological technique and contains brief directions for the fixing, staining, and mounting of specimens. The illustrations are schematic but clear and will serve as models for the drawings the student is expected to make of what he himself sees under the microscope. This book, like the other manuals of the series, is well adapted to the purpose for which it is intended.

Dritte Bericht über Salvarsanbehandlung, aus dem Kaiserlichen Marinelazarett Kiel-Wik. Von Dr. Gennerich, Marine-Stabsarzt. Mit zwei Kurventafeln. Price, 2.40 marks. Berlin: Verlag von August Hirschwald, 1911.

This pamphlet of eighty pages gives the result of treatment of some 340 patients with Ehrlich's salvarsan. Numerous clinical histories are given, the intoxication phenomena following salvarsan are discussed and a comprehensive study of the Wassermann reaction in the patients treated is given. Gennerich's opinion of the new remedy is, in general, a very favorable one. He agrees with Wechselmann that impure saline solutions are responsible for most of the untoward reactions after intravenous use of salvarsan and not the remedy itself.

The House Surgeon's Vade-Mecum. By Russell Howard, M.B., M.S. (Lond.), F.R.C.S. (Eng.), Surgeon to Poplar Hospital; Assistant Surgeon London Hospital; author of "Surgical Nursing," etc. Illustrateed. New York and London: Longmans, Green & Company.

This is a small but useful work on minor and emergency surgery. It is written for the use of hospital internes; and it will doubtless be of service not only to them, but also to the general practitioner, who, while not professing to be a surgeon, has often to do much surgical work. The author has made a judicious selection of topics and has handled his subject in a masterly way. It is gratifying to note that, in the list of books used for reference, the author makes mention of several well-known American text-books.

Untersuchungen über die Struktur der Blutzellen. By Alfred v. Decastello, M.D., and Alexander Krjukoff, M.D. With eight colored plates. $4.00. Berlin and Vienna: Urban & Schwartzenberg. New York: Rebman Company, 1911.

There has been in the last few years a greatly increased interest in the study of the finer morphology of the cells of the blood and not a few researches, the object of which has been to clear up the genetic relations between the leucocytes and their parent cells in the bone marrow and lymph nodes, have been published.

Some of the methods employed have been chemical, as in the well-known indophenol reaction which serves to separate cells of the bone marrow group from cells of the lymph node group. Other studies, like the present work, are based simply upon the extensive histological investigations of a large quantity of material, using the more or less conventional methods of fixing and staining the cells. The conclusions reached are not wholly in accord with those generally held by the majority of workers with the blood. The authors hold that the idea that the blood cell, especially the nuclear portion of the cell, is surrounded by a sort of membrane, through which osmosis takes place, is incorrect and instead they regard the nucleus and cell body as composed of a net work of fine, interlacing fibers; that these fibers are continuous between the nucleus and the protoplasm of the cell; that the granules seen in the leucocytes are not secretion particles, but nodes in the fibrous net work; that the blood plates arise from the cytoplasm of the leucocytes and show differences of structure depending upon the type of cell from which they have arisen. Some of these views are not wholly original. For example, the idea that the azur granules found in the lymphocytes are fragments of nuclear material which is broken off from the nucleus and lies free in the cell body has long been held. The assumption that the whole cell is a network of fibers will certainly not be generally received. The origin of blood plates is also probably not from leucocytes, but from the megacaryocytes of the bone marrow, as has been shown by J. Homer Wright. A series of eight colored plates adds very much to the value of the book.

Vorlesungen über Frauenkrankheiten. Aus der Praxis fur die Praxis. By Dr. Karl Abel. With ninety-three illustrations, some in color. Price, 14 marks. Berlin: Oscar Coblentz, 1912.

This book presents a series of lectures delivered by the writer to medical students, which are based on an experience of twenty years in gynecological practice. The entire subject-matter of the diseases of women is delivered in a very complete and easily read form, including all the known and adopted facts. The desire of the author is to present the most practical aspects of the subject as they would come under the notice of the general practitioner, so that the descriptions, except when necessary, are not burdened with detailed references to etiology, pathology, or treatment. The accounts given of most of the usual gynecological conditions are very complete, however, and the section devoted to the subject of abortion is particularly so. The author does not advocate any radical treatment of this condition as regards curettage, advising dilatation and removal of the remnants with the finger rather than an instrument. There is also an excellent concluding chapter on appendicitis in the female. The doctor states by way of introduction that gynecology should be considered as the study of woman and not exclusively as a study of the diseases of the female genitals. This attitude is consistently followed throughout the book and may be regarded as almost a new departure in text-book literature. The work is satisfactorily printed and illustrated, but the presentation of the subject-matter in lecture form will scarcely appeal to American readers.

Surgical Applied Anatomy. By Sir Frederick Treves, Bart. G.C.V.O., C.B., LL.D., F.R.C.S., Sergeant Surgeon to H.M. the King; Consulting Surgeon to the London Hospital; late Lecturer on Anatomy at the London Hospital. Sixth Edition, revised by Arthur Keith, M.D., LL.D. Aber., F.R.C.S. Eng., Hunterian Professor and Conservator of the Museum, Royal College of Surgeons of England; formerly Lecturer on and Senior Demonstrator of Anatomy at the London Hospital; Examiner in the Universities of Aberdeen, Cambridge, etc. Illustrated with 137 Figures including 58 in color. Price $2.50. Philadelphia and New York: Lea & Febiger, 1911.

After a book has enjoyed a successful career for more than a quarter of a century it is hardly necessary to do more than announce a new edition. There are several reasons why this work has been so popular. Its intrinsic merits, attractive style, small size and price, and the skill and reputation of its distinguished author all contributed to its early success, and all still remain in connection with this new edition. The chief alterations relate to the glands of internal secretion, to the lymphatic system, to the anatomy of the abdomen, and to new facts which have been discovered by the use of the *x*-rays in examining the human body. Thirty-five new illustrations have been introduced. Many a busy practitioner finds his recollection of anatomical facts growing dim; the present volume is admirably adapted to encourage a survival of the fittest of these facts, and also to refresh the memory on such anatomical details as have the most direct bearing on practice. In spite of recent competitors (all more pretentious and higher priced), Treves' Applied Anatomy continues to lead; and it is one of the very few books, in any field that has held undisputed supremacy for nearly thirty years.

TEXT-BOOK OF OPHTHALMOLOGY. By Dr ERNST FUCHS, Professor of Ophthalmology in the University of Vienna Authorized Translation from the Twelfth Revised and Greatly Enlarged German Edition, with Numerous Additions. By ALEXANDER DUANE, M.D., Surgeon, Ophthalmic and Aural Institute, New York. With 441 Illustrations. Fourth Edition Price $6.00. Philadelphia and London: J. B. Lippincott Company, 1911.

THIS new translation of Professor Fuchs' well-known treatise on diseases of the eyes is made from the twelfth edition of the German original. It contains a very interesting and valuable introductory chapter, prepared for that edition, on the general physiology, pathology, symptomatology, and therapeutics of the eye. There are also numerous changes and shorter additions in the other sections, and throughout the work the brief but judicious and helpful comments and additions by the translator add very greatly to the value of the treatise as a textbook for general practitioners as well as ophthalmologists. A number of the illustrations also (some of them excellent colored plates) have been inserted by Dr. Duane.

MINOR AND EMERGENCY SURGERY. By WALTER T. DANNREUTHER, M.D., Surgeon to St. Elizabeth's Hospital and to St. Bartholomew's clinic, New York City; ex-House Physician and Surgeon Jersey City Hospital, etc. Illustrated. Philadelphia and London: W. B. Saunders Company, 1911.

THIS book has been prepared expressly for hospital internes and ambulance surgeons, and is devoted to some of the details of minor surgery. The work is of a very elementary character, and, as a rule, an interne in our best hospitals would be expected to know much more than is contained in this volume. It might possibly be used as a handbook by medical students who are beginning to attend surgical clinics in the out-patient department. Some of the advice given is good, but some of it is in poor taste; *e.g.* "Don't fail to respect a patient's religion, *especially if he is a Catholic*;" why these last six words? Gibney's dressing, if applied as shown on page 54, might lead to disastrous results.

LEHRBUCH KLINISCHER UNTERSUCHUNGSMETHODEN FÜR STUDIERENDE UND ARZTE. By THEODOR BRUGSCH, M.D., and ALFRED SCHITTENHELM, M.D. $4.25. Berlin and Vienna: Urban & Schwarzenberg. New York: Rebman Company, 1911.

THE prompt appearance of a second edition of this textbook of clinical methods of investigation is an index of its popularity and, to some extent, of its usefulness to the medical public. The custom in Germany has been to include in one volume not only the physical methods of examining patients, but also a good deal of what is commonly designated clinical pathology. As a result both phases suffer from necessary compression in order to keep the book within the limits of a size which can be conveniently handled. The danger is that such a book becomes a mere quiz compend, reviewing everything, but teaching little. The authors evidently appreciate this dilemma, as they state in the preface that they have been compelled to assign to another volume, to appear later, a large number of special methods of investigation, which can only be carried out by trained workers in especially equipped laboratories.

This is the first acknowledgment from Germany that the problem which for some time past has occupied physicians and laboratory workers of the larger hospitals must be ultimately solved by a division of labor. Until recently the chief of a great German clinic usually felt himself quite competent not only to direct the physical diagnosis of the ordinary routine examination of the patients, but also to direct the themes for investigation in chemistry and pharmacology; an attitude which has not infrequently added but little to the subject so studied. It is manifestly impossible at the present day for any physician, even if he devotes himself entirely to the study of the ward patients, to be in any way in touch with the details either of chemistry, pathology, or bacteriology, or to be able to direct research in those lines. He will have enough to occupy his time if he keeps up with the improvements in physical diagnosis based upon the discoveries in physiology. The inevitable split then between the laboratory and the wards is coming in Germany as a mere part of our increased specialization in internal medicine. The separation must never be complete, but there is room for a number of coordinated workers in clinical medicine, each with his special laboratory training, the advantages of which he must apply to the investigation of his cases.

This attempt to cover too large a field limits the value of this otherwise excellent volume. As a book to recall the main points of knowledge already acquired it is excellent; but it is evident to any one that, for example, it is difficult to become an expert in the interpretation of *x*-ray plates of the viscera by reading forty-two pages devoted to the *x*-ray. For example, the quoted work of Holzknecht on the form of the normal stomach is already being questioned. Nor will to-day the statement be accepted that the tapeworm. *Tænia nana* chiefly occurs in Italy and Egypt The American reader will be disappointed in finding nothing, in the part on infection and immunity, on the immunity induced by dead bacteria, the so-called vaccines.

On the other hand, these defects which have been pointed out are largely compensated from the student point of view by the extremely clear and compact way in which facts are presented, so that the work affords a survey of scientific medicine in most compact form and therefore should enjoy a very wide popularity.

THE BACILLUS OF LONG LIFE. A Manual of the Preparation and Souring of Milk for Dietary Purposes, Together with an Historical Account of the Use of Fermented Milk, from the Earliest Times to the Present Day, and Their Wonderful Effect in the Prolonging of Human Existence. By LOUDON M. DOUGLAS, F.R.S.E. With 62 Illustrations. Price $1.50. New York and London G. P. Putnam's Sons, 1911.

ONE may read this book with interest, even though he may not have an unquestioning belief in the theory expressed in the title, for it gives much information regarding the use of milk, especially soured milk, by the Arabs and the peoples of southeastern Europe. The chapter on the preparation of soured milk in the house contains minute directions for the preliminary treatment of the milk as received from the dairy, the inoculation with cultures of lactic-acid bacilli, the maintenance of the proper temperature, and the preservation of the soured product. Objection may be taken to the recommendation to sterilize the milk by boiling in preference to pasteurization, for the taste of boiled milk remaining even after it is soured is objectionable to many persons, and moreover boiling is believed by many to impair the nutritive value of the product. Pasteurization requires but little more care than boiling, and a properly pasteurized milk will sour as readily after inoculation with an active culture as will boiled milk. The advice to use only separated milk is good; if the fat is desired in individual cases it can be applied by adding pasteurized cream to the soured milk at the time of taking.

RETINOSCOPY (OR SHADOW TEST) in the Determination of Refraction at One Meter Distance with the Plane Mirror. By JAMES THORINGTON, A.M., M.D., Author of Refraction and How to Refract: The Ophthalmoscope and How to Use It; Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Ophthalmic Surgeon to the Presbyterian Hospital; Ophthalmologist to the Elwin and Vineland Training Schools for Feeble-Minded Children. Sixth Edition, Revised and Enlarged. Sixty-one Illustrations, ten of which are colored. Price $1.00 net. Philadelphia: P. Blakiston's Son & Company, 1012 Walnut Street, 1911.

THE fact that this work is now in its sixth edition is sufficient evidence of its worth and popularity. The book is well printed and well illustrated. The subject is presented in a clear and concise manner, devoid of much theory and abstruse formulæ. It is very well adapted for the use of the student, as the facts presented can be readily understood.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. December 1, 1911. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger.

THE current number of Progressive Medicine contains articles on: Diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, by R. S. Lavenson; Diseases of the kidneys, by J. R. Bradford; Genitourinary diseases, by C. W. Bonney; Surgery of the extremities, shock, anesthesia, infections, fractures and dislocations, and tumors, by J. C. Bloodgood; and Practical therapeutic referendum, by H. R. M. Landis. The present number completes the thirteenth year of this publication, and it is second to none in its usefulness to the general practitioner who would keep abreast of the advances in medicine and surgery.

Society Reports.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, Held January 15, 1912

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

Election of Officers.—The following officers were elected: *President*, R. W. Wilcox; *Vice-President*, R. E. Van Gieson; *Corresponding Secretary*, F. C. Raynor; *Treasurer*, A. E. Gallant; *Chairman for the Borough of the Bronx*, N. B. Van Etten; *Chairman for the Borough of Brooklyn*, R. E. Coughlin; *Chairman for the Borough of Queens*, L. H. Moss.

Some Ocular Conditions Dependent Upon Gastro-intestinal Disturbances.—DR. J. SCOTT WOOD, in this paper, said it was now an accepted belief on the part of many ophthalmologists, amounting almost to a feeling of certainty, that a large number of affections of the eye were directly due to gastrointestinal fermentation and putrefaction, and that the resultant product of this action in the alimentary tract was a toxin which, upon being liberated into the general circulation, caused pathological phenomena in the eye and elsewhere. Autointoxication in its relation to the eye had, however, received little or no attention in our text books, and we had to go to the general ophthalmic literature for anything definite regarding it. Having quoted from De Schweinitz and various other authorities, he went on to say that the lids, conjunctiva, cornea, sclera, iris, retina, choroid or optic nerve might be attacked, and while we did not know what they were, yet, when analysis of the urine and examination of the end-products of digestion were made, we found many evidences of imperfect metabolism, faulty assimilation and elimination and putrefaction. Sties and blepharitis, occurring in those showing evidences of intestinal putrefaction with persistent indicanuria, might be regarded as resulting from a state of autointoxication; while phlyctenular conjunctivitis was a disease dependent more upon diet and bowel irregularities than anything else. Many of these cases, he believed, were amenable to appropriate measures, without any local treatment whatever. While in a high percentage of cases of affections of the cornea and sclera the condition was due to trauma, infection from without, syphilis, tuberculosis and malaria, many of the types of so-called nutritional disturbances accompanied by corneal inflammation and ulceration apparently had back of them a toxic condition of the alimentary tract; so that the eye trouble persisted as long as the toxemia remained. Condensed milk, candy, crackers, cake, pastry, and other indigestible foodstuffs were the direct agents of fermentation and putrefaction, and it seemed to him that we were too prone to rely upon local treatment here, and not pay sufficient attention to the physical condition. Scleritis and episcleritis were said to depend frequently upon some form of autointoxication, and in every case where gout, rheumatism or syphilis were excluded the cause was to be looked for in the intestinal tract. As to the ocular muscles, he knew of no authenticated cases of paresis or paralysis due to this cause, but if ptomaine poisoning could give rise to such paralysis it seemed reasonable to suppose that autotoxemia might also. That many of the so-called tobacco-alcohol amblyopias were associated with intestinal putrefaction seemed beyond question, and the part played by gastritis and the accompanying catarrhal inflammation was interesting, although our present knowledge regarding it was somewhat vague. In this connection the speaker related a case of his own which indicated that simple autointoxication was capable of causing amblyopia. Since the discovery of the Wassermann and von Pirquet reactions for syphilis and tuberculosis the etiological classification of affections of the uveal tract ought to be much simplified, and he was convinced that it would now be found that here syphilis and tuberculosis would not now occupy such prominent places as etiological factors as heretofore. That some, and perhaps many, cases of iritis, iridochoroiditis and choroiditis were due to gastro-intestinal disturbance seemed beyond doubt, for in this class of cases perhaps more than any other were gastro-intestinal symptoms prominent. By way of illustration a case was related presenting a type of central choroiditis in which the patient was markedly neurotic, dyspeptic and constipated and gave evidence of intestinal putrefaction. In another instance of central choroiditis, in a patient of Dr. Kirkendall of Ithaca, the eye trouble was proved to be due to chronic fibroid degeneration of the appendix resulting from colon bacillus infection; the choroiditis disappearing after the removal of the appendix.

THE PRESIDENT, DR. WILCOX, said that Dr. Wood's paper was a scholarly and masterly presentation of the whole subject, and one which deserved most careful consideration by practitioners generally, and particularly by those paying special attention to affections of the gastrointestinal tract. It contained a vast mass of material which could be obtained only with great difficulty, and from a great variety of sources, and he therefore thought the author deserving of much praise for his painstaking labors, as well as of an adequate discussion of the paper.

DR. NELSON L. NORTH said there was one practical point which was worthy of consideration, the enormous increase of late in the consumption of chocolate. This article was, no doubt, a good thing in itself, but in the very great quantities in which it was given to children at the present time it was certainly productive of much evil as one of the sources of the troubles under consideration. Another point: In adults why was it that the malt liquors especially were responsible for this trouble? We sometimes found it necessary to forbid patients the use of beer, but it was plainly not on account of the alcohol in this beverage, since the spirituous liquors contained so much more of this agent yet did not cause so much reflex irritation of the cornea and conjunctiva.

DR. WILCOX suggested that it was perhaps the picrotoxin now so often substituted for hops in the manufacture of beer which was responsible for the trouble. It was certainly a fact that picrotoxin was capable of playing many pranks with the nervous system.

DR. ANTHONY BASSLER said that of late the ophthalmologists, laryngologists, dermatologists and other specialists were paying distinctly more attention than formerly to states of excessive chronic intestinal putrefaction, on account of the recognition of their etiological importance. From the nature of the various substances manufactured in the gut, which were reabsorbed into the circulation, it was plain that functional and structural change must take place in the body. Having enumerated some of them, he said that in these chronic intestinal conditions more than the diet had to be considered, for errors of motility and secretion might have much to do with a bacterial change. It was naturally to be expected that the delicate structures of the interior of the eye, being of a highly specialized type of neurovascular combination, would sometimes be severely affected.

DR. FRANCIS VALK said that in a number of the conditions mentioned in the paper he did not believe that gastrointestinal disturbances had anything to do with the etiology. He would certainly leave out all affections of the lid, the conjunctiva, and the cornea as due to autointoxication. On the other hand, he did recognize that many cases where the retina and other interior structures were involved were dependent upon this condition. Here we first had to exclude tuberculosis and syphilis, and thus,

by a process of elimination, we were compelled to attribute the trouble to the gastrointestinal tract.

Dr. A. Ernest Gallant said he had made it a rule to refer the patient to an ophthalmologist for examination whenever he found any eye trouble present, and in nine-tenths of the cases the report was that no condition was discovered which would not be improved by the treatment of the affection for which she had consulted him (Dr. Gallant). Autointoxication was very apt to occur from the retention of feces too long in the intestinal canal, and this was largely because the feces did not have sufficient bulk; a result due to the exclusion from the food of the husks of the wheat, the skins of grapes, and other similar material. To correct the condition he had for some time been employing bran, and with very satisfactory results.

Dr. Wilcox said that Professor Mendel of Yale had suggested agar agar for the same purpose for which bran was employed, and clinical experimentation in the matter was carried on by Dr. Gompertz of New Haven. The results had been excellent, after two years' trial, but the difficulty was to get the agar agar into the patient. Gompertz recommended that it should be used in the same manner as a breakfast cereal, but its extreme glutinousness rendered this objectionable, and the only way in which he (Dr. Wilcox) could get patients to take it at all was in the dry form.

Dr. Bassler said he had used a great deal of agar agar, giving it in half-ounce doses. He was accustomed to have an ounce and a half of it cooked in a steamer with perhaps six ounces of oatmeal. This served for three doses, and was eaten with cream or fruit juice.

Dr. Wood, in closing, said he could not doubt that the lids, conjunctivae and other coats of the eye were affected by gastrointestinal conditions. He knew of no more striking disappearance of a pathological condition than was frequently to be observed in the phlyctenular conjunctivitis of children when strict regulation of the diet and prompt bowel evacuation had been instituted. The scleral types of disease were on more debatable ground, though in cases in which neither syphilis nor tuberculosis could be detected, and in which increased amounts of indican, urobilin, skatol and other waste products were to be found in the urine, he thought they should be logically considered as of gastrointestinal origin.

Eye Training for the Cure of Functional Myopia.—Dr. W. H. Bates, in this paper, arrived at the following conclusions: 1. Functional myopia occurred frequently. It was associated with many other eye defects and, when it disappeared, these were usually benefited. 2. Functional myopia was produced in all normal eyes by improper efforts to see. 3. School teachers, physicians and others had relieved functional myopia by eye training or education. 4. The Snellen test card was found to be the best distant object for training the eye for the cure of functional myopia. In functional myopia, he said, the eye was adjusted for near vision without permanent elongation of the optic axis, as was the case in true myopia. The diagnosis had been made with the air of the ophthalmoscope, but many cases had been recognized with less difficulty and more accurately by retinoscopy. The local and prolonged use of atropine had not always relieved the condition. Functional myopia had been found, in varying degrees, in more than ten thousand school children, where it was responsible for nearly all the eye pain, asthenopia, defective vision, headaches and irritability of the children. It was frequently found among farmers, day laborers, mechanics, sailors and professional men and women. When they regarded large objects most persons with normal eyes were unconsciously functionally myopic, but when regarding small objects clearly, or reading the 20 line on the Snellen card at twenty feet, the normal eye was adjusted accurately for distant vision and was at rest. These facts were demonstrated by simultaneous retinoscopy. When entering school, children usually had normal vision, but in a short time acquired functional myopia. In one class-room of 40 pupils, 6 to 8 years old, the eyes of whom were first examined in the spring of 1903, it was found that all had difficulty in reading the Snellen card. Thirty were relieved in less than five minutes, after they had been shown, with the aid of the test card, how to regard distant objects without an accommodative effort. Relapses were prevented and the remaining ten defectives were cured by the teacher by means of similar exercises in distant vision. This teacher used the card continuously for eight years afterward, and had reported that in consequence of this training no more children in her room acquired defective vision. The same success in relieving or preventing functional myopia was also achieved by more than fifty other teachers. Numerous other benefits were observed, and the teachers themselves found relief from eye-strain by the use of the card. A Snellen test card was placed permanently in all the class rooms, and the exercises in distant vision required less than half a minute daily. The directions given to the children were: Read the smallest letters you can see with each eye separately at a distance of more than ten feet. Most persons with functional myopia were unconscious of the effort made to see distant objects, and they were benefited after they understood that an effort lowered vision. The exaggeration of the unconscious effort was usually followed by a greater relaxation of the effort to see distant objects, and the simultaneous use of the retinoscope indicated improvement. A large amount of compound myopic astigmatism 4 D. in a normal eye had been observed with the retinoscope during the time the patient made the effort to read the Snellen card with the lids partly closed. With each succeeding effort the myopia became less, until it disappeared, and the patient no longer made an effort to read the card with the lids partly closed. The patient was instructed in eccentric fixation; when the normal eye read one letter of the line marked 20 on the card, at twenty feet, the eye was directed straight to the letter. In functional myopia eccentric fixation was frequently found either in one or both eyes, and such cases were not benefited until after it was corrected. In order to teach the patient how to regard objects by central fixation he was first shown how to exaggerate it. An illustrative case was cited, that of a girl of 14, whose left eye was normal, but with right vision, four fingers at 4 feet, amblyopia exanopsia, convergent squint, and functional myopia. Under training with the aid of the Snellen card she obtained binocular vision, and was cured in two weeks; the result being permanent after eight years. Other cases also were described by Dr. Bates, and he stated that a number of physicians had visited the eye clinic at the Amity Dispensary and, after diagnosing functional myopia, had observed the prompt relief afforded by the eye training mentioned.

Dr. Wilcox said that all must have observed the large number of children now wearing glasses. Among the poor it seemed to be an object of pride that these should be of the best, and it was not an uncommon thing to see a poorly clad little girl with gold spectacles and carrying a large bundle of books. Now, if anyone could obviate this state of affairs, he would certainly deserve a great deal of credit.

A. H. Yoder, lecturer on Child Sociology in the New York School of Philanthropy, said that as a sociologist he was in entire accord with the sentiment expressed by the President. Most children were long-sighted before they went to school, but if their eyes were examined some time after they had been there it would be found that a change had occurred and that they had now become myopic. Therefore, it seemed to be evident that there was something in the school situation producing this result. Accord-

ing to his observation this eye defect reached its maximum about the age of ten years; after which it began to decrease, though it might not disappear. For the purpose of correcting the myopia and its attendant evils a method had been tried in a city of North Dacota, and the evidence in its favor was positive as far as it went. The eyes of over 8,000 school children were examined three times, and the results were found gratifying. If, then, Dr. Bates had offered a simple method of teaching children how to see, we were certainly under obligations to him.

Dr. C. Ward Crampton, Director of Physical Training in the New York City public schools, said he had to confess that at first he was not very much impressed with Dr. Bates' ideas, but on becoming practically acquainted with his method he had become more and more convinced of their probable importance. If the "if" to which the president had given expression were done away with we had here something of exceeding great importance, and he wanted to be one of the first to recognize this. In New York there were 700,000 school children, for whose physical condition he was in a measure responsible. If all were well when they first came to school, and if later from 30 per cent. to 60 per cent. were found to be suffering from defective vision, then we wanted to do something to remedy this condition of affairs. The question therefore arose, Shall this new method be put into operation in the schools? Dr. Bates said that half a minute a day was sufficient for carrying it out; but the aggregate time spent would amount to 133 years, while the teachers' pay would sum up $31,000. Here again, the "if" which has been mentioned presented itself, and he wanted advice from the medical profession on this subject.

Dr. J. Scott Wood said that it was practically impossible for him to discuss this subject, as it was one about which he knew nothing. He had been somewhat confused by the term "functional myopia" and was at a loss to know just what the writer of the paper meant by it. In one place he spoke of the effort on the patient's part to see, whereby frowning and wrinkling the brow were indulged in, thus inducing a "functional myopia," as he termed it; and, again, from other parts of the paper, one might infer that in some way accommodative spasms might be held to be the cause of it. At any rate, he would ask Dr. Bates if he ascribed this induced "functional myopia" to pressure of the lids upon the eyeball and bringing about an elongation of its anteroposterior diameter, or to an accommodative spasm, or to both. In reading his paper, that at least would seem a reasonable inference. In order that Dr. Bates' contention might be proved or disproved, he thought the patients in public institutions or elsewhere, upon whom this method was to be applied, should be examined by competent and disinterested ophthalmologists, both before and after Dr. Bates had them. There was one point, however, which he could not understand, namely, why should a normal eye, under conditions of illumination, look in an abnormal manner at a small object (which it could readily see) at 15 or 20 feet away? One might just as well expect to see a man with sound legs limping down Fifth Avenue. The claims of Dr. Bates were certainly novel in the extreme, and we should investigate them with an open mind and in a spirit of fairness.

Dr. Aquin S. Kelly said that Dr. Bates' paper was eminently a physiological one, treating of an aspect of ophthalmology which most eye men were prone to disregard, and it would surely shake the theories of many who read it. After listening to his statistics one could not help wondering whether a thoroughly conscientious refraction was possible without the use of atropine (1 per cent. for a week or more), whether we were justified in depending on the employment of homatropine in any case of refraction, and what would be the effect of this paper on the "refractory" villains who prescribed glasses for their patients, young and old, without the use of any mydriatic. The statistics on the prevalence of functional myopia were most surprising. Every year he himself saw hundreds of school children refracted, and he did not recall meeting with more than three cases of functional myopia, or what was commonly known as spasm of accommodation, in the past six years. He could not see, therefore, how more than a very small proportion of children could derive any benefit whatever from Dr. Bates' method of treatment. It seemed to him, judging from his observation of boys at play at the present time, that 90 per cent. of them pitched, batted, and caught, and directed the flight of a snowball quite as well as we ourselves used to do. The discussion of the question of eccentric fixation, Dr. Kelly said, was beyond him, as in all his experience he had never met with a person who was so lazy or stupid as to permit himself to see double if he could avoid it.

Dr. B. W. Key said that given school children with eyes nearly normal, known process from 12 to 18 D. of accommodation, and placed under conditions necessitating constant accommodation for near objects, living in cities where their home surroundings seldom allowed twenty feet for relaxation of the accommodation, and add to this the increased requirements of the modern school, with its stress of close application and competition—and it would not be difficult to appreciate that the development of functional and axial myopia was tending to increase. It was rather surprising to learn, however, that there had been observed so many cases of functional myopia as reported by Dr. Bates, and especially that these cases had been relieved in so short a time; the mere regarding of the Snellen test chart at twenty feet for half a minute daily being the only treatment necessary. More astonishing still was the report of the relief of cases of axial myopia as high as 2.50 D. when tested by the retinoscope under the influence of atropine. In fact, he was quite sceptical in regard to some of the cases reported. Having in mind the simple treatment for functional myopia advocated by Dr. Bates, he had during the last ten days made some observations on those cases with nearly normal myopic eyes, about ten in number, which he had had the opportunity of examining in that time. He confessed he could not report very satisfactory results; but one case was worth mentioning. It was that of a strong healthy boy of sixteen, a student at Lawrenceville, who was wearing for each eye a 1.25 sphere, prescribed for him by a well-known ophthalmologist of this city. He complained of photophobia, asthenopia, and twitching. At first on regarding the Snellen chart he saw O. D. 20/200 and O. S. 20/100, without his glasses, and on being instructed how to read without making any effort he gradually obtained O. D. 20/70 + 1 and O. S. 20/40 + 1. He regretted that it was not possible in this case to use atropine at the time of the examination, but the patient was obliged to return to school. He felt sure that this was the type of case Dr. Bates referred to as being so common among school children, but he also felt confident that the proper use of atropine with retinoscopic, ophthalmoscopic, and perhaps ophthalmometric agreement would relieve this boy of his symptoms.

Dr. Bates, in closing, said that as a rule children when they entered school had normal vision, but later acquired myopia. He had seen many functionally myopic children of eight or ten become normal or emmetropic under the treatment described, and entirely without the aid of glasses. The eyes of a young child were usually normal when looking at its mother, but were apt to become functionally myopic if it looked at a stranger. In any child myopia could be produced by an improper effort to look at a distant object. He had tested the eyes of school children by having them look at all sorts of objects, stationary and moving, and at various colors. To arrive at correct conclusions in this matter it was necessary to make repeated observations

In the kindergarten we usually found normal eyes, but children in the first, second, and third grades at school were almost all functionally myopic at times. Moreover, astigmatism was acquired by them just as the myopia was. The people of uncivilized countries had normal vision, because they needed to practise distant vision in order to provide food and to protect themselves from enemies. He had endeavored to find out the cause of myopia so that he might devise means for its prevention, and he had succeeded. Exercise in distant vision with the aid of the Slennen test card had been successfully employed continuously for eight years in the public schools of Grand Forks, N. D. This was the first success in the prevention of myopia to be published. In reply to Dr. Wood he would say that he had not made the assertion that functional myopia was caused by pressure of the lids upon the eyeball.

NEW YORK ACADEMY OF MEDICINE

SECTION ON MEDICINE.

Stated Meeting Held December 19, 1911.

DR. HENRY STUART PATTERSON IN THE CHAIR

Adrenal Transplantation, Followed by Symptoms of Adrenal Hypersecretion.—Dr. ROBERT T. MORRIS presented a case report of a patient with Addison's disease, for whom he had transplanted an adrenal gland.

The patient was admitted to the medical service of Dr. Quintard at the Post-Graduate Hospital on October 1, 1911. Dr. Pfletschinger had asked Dr. Morris if he could transplant an adrenal gland for the purpose of furnishing internal secretion, to take the place of the patient's glands, which were supposed to be undergoing destruction from tuberculosis. The patient presented the customary symptoms of a rapidly progressing case of Addison's disease. Dr. Morris believed that transplantation of suprarenal glands from a monkey would not be desirable because of the tissue antagonism existing between species, a condition familiar to experimenters in the field of transplantation of structures. Antagonism being less between individuals of a species, it was decided to obtain a human suprarenal gland for transplantation, and some time was lost waiting the opportunity. Two or three men who had been suddenly killed were not desirable as subjects for furnishing adrenal glands, but on the morning of October 25 a suprarenal gland was removed aseptically by Dr. Otto H. Schultze from a girl, twenty-two years old, whose throat had been cut the night previously. Dr. Schultze placed the gland in salt solution. It was kept in the refrigerator until 6:30 P. M., and Dr. Morris transplanted it to the omentum of the patient with Addison's disease. The endothelial covering was brushed away from a suitable space on the omentum, and the suprarenal gland sutured snugly into a pocket at this point. The entire operation was done quickly, twenty minutes being consumed in the entire process, and with little handling of viscera. At midnight the patient's temperature was 98°, pulse, 104, respiration, 24, indicating very little disturbance from the operation, and the following day at 4 P. M. the temperature was 98°, pulse, 100; respiration, 32. At 8 o'clock there was a marked change in the vital signs—the temperature was 100.8°, pulse, 136; respiration, 32, and at 11 o'clock the patient died.

Dr. Morris asked if this change in the vital signs, and rapid dissolution, meant a sudden liberation of internal secretion from the transplanted gland, through saprophytic or other destructive processes, resulting in giving the patient an overdose of contents of the gland. He wished to know if in the opinion of the members the operation might be repeated in a stronger patient, without anticipating such a result as occurred in this case.

Dr. HAVEN EMERSON could not see what evidence there was to show that the patient's death was caused by anything that had to do with adrenal gland products. Patients who died of Addison's disease had a very poor supply of blood to their vital centers. The operative procedure, however, might have hastened the death of this patient.

A Case of Septic Endocarditis.—Dr. NATHANIEL BOWDITCH POTTER presented specimens and a chart to illustrate what he wished to report. The specimens were an hypertrophied heart, showing vegetations upon the aortic valves; the kidneys, showing a chronic productive nephritis, and sections from the brain. The patient had a septic endocarditis with clinical manifestations of an acute uremia. He was admitted to the City Hospital last October. He was fifty-eight years old. He had been a hard drinker and had syphilis thirty years ago. In childhood he had diphtheria and scarlet fever. He first began to complain six months before admission to the hospital of shortness of breath and swelling of his legs. He had an ulcer on his leg which had healed; and later an eruption on his legs. When admitted to the hospital he complained chiefly of shortness of breath. His blood pressure ranged from 150 to 180. No blood culture was taken. He soon developed Cheyne-Stokes' respiration, and ten days later died in coma. The ventricles of the brain were dilated, contained a large amount of serum, and over the convexity of the brain was found an accumulation of fluid; there were also flattened convolutions and a great many hemorrhages and thromboses in the vessels of the pia arachnoid.

Noguchi's Luetin Reaction: A Brief Description and Estimate of Its Practical Value.—Dr. H. F. L. ZIEGEL said that the theoretical conception on which the luetin test was based was one which many investigators must have had in mind before Noguchi made its realization possible by discovering a means of growing the *Treponema pallidum* in pure culture. For instance, in an article on "allergy" von Pirquet had prophesied: "I personally feel quite sure that it will be possible to make the diagnosis of syphilis by cutaneous and subcutaneous inoculation as soon as the syphilis virus can be obtained in pure cultures." Dr. Ziegel offered the following summary: "(1) The luetin test is a simple, harmless procedure, consisting essentially of the intradermatic injection of a carbolized emulsion of sterile cultures of *Treponema pallidum*. (2) The reaction is negative in normal and nonsyphilitic individuals, and in various diseases, including tuberculosis, pneumonia, typhoid fever, malaria, carcinoma, eczema, and psoriasis. (3) The test can already be accepted as of considerable negative value. As compared with the von Pirquet reaction, the latter gives more than 50 per cent. positive reactions in apparently nontuberculous adults, whereas the luetin test is constantly negative in both adults and children who are clinically and serologically nonsyphilitic. (4) The positive value of the test appears to be more limited. A positive reaction is rarely obtained in primary syphilis and seldom in secondary syphilis." Noguchi found the test unsatisfactory in parasyphilitic conditions. Whether the negative reactions usually obtained in patients practically cured of syphilis indicated lasting suppression of the disease remained to be determined. In hereditary and tertiary syphilis, however, Noguchi obtained positive reactions in more than 90 per cent. of the cases.

A Limited Typhoid Epidemic Traced to a Typhoid Carrier.—Dr. C. N. B. CAMAC reported this epidemic because it presented what to him were several valuable lessons in regard to a typhoid carrier and the transmission of the typhoid bacilli through drains. In 1910 there was a sharp epidemic of the disease which broke out in a convalescent home at Murray Bay, Canada. Convalescents were taken there from Quebec and from Montreal. During the month of July there were eleven cases. The home was supplied with water that came largely from

a spring, although some came from a source higher up. The question of the origin of the infection brought up was: "Did water or did milk cause the outbreak?" The water was found to be contaminated, and the supply was cut off; the cases then ceased to appear in the home. This spring was on the high road, and it was possible to contaminate the stream from passers-by. The ground was examined very carefully. Dr. Camac drew a diagram of the water supply, showing how the infection was carried. Two summers before, in 1909, Dr. Henry had a cook who gave signs of having a colitis and had a femoral phlebitis. The cook was sent to the Montreal General Hospital, and did not return until October. During the time in the hospital she had a positive Widal reaction. The cook went back to the home and there had two attacks of colitis. The following summer the cook again returned to Murray Bay and occupied a house on the hill just above this spring. A drain ran across the road and under it; most of the village had a submerged drain. The spring supplying the home lay on the opposite side, where it ceased to be a surface drain. There was no doubt but that the woman contaminated the drain during the summers of 1909 and 1910. In July, 1910, there developed eleven cases of typhoid fever. When the water supply was cut off from the home no more cases developed. The town and house supply of water was good; that from the spring was bad. The water above the spring and below the spring was good. But the trouble was found to be in a break in the drain. There was quite a large crack found. There were three communicating exits in this drain, and in any one of them the typhoid germ could gain access from the house which was occupied by this typhoid carrier for two summers. Among the valuable features reported were (1) that contamination could come about by means of a surface drain for thirty-five or forty feet; (2) the attacks of colitis were capable, through the discharge of the bacilli, of acting as an active agent in producing this epidemic of eleven cases and one death.

An Automatic Device for Reading Systolic and Diastolic Blood Pressures.—Dr. B. RAYMOND HOOBLER presented and described this device. (See MEDICAL RECORD, December 30, page 1323.)

Report of a Case of Septic Endocarditis, Thrombosis of the Aorta, and a Bicuspid Aortic Valve.—Dr. LINSLEY R. WILLIAMS reported this case because it presented unusual difficulties in diagnosis from a clinical and bacteriological standpoint, an unusual congenital cardiac defect, and unusual pathological conditions. The patient was a girl 13 years old, admitted to the hospital August 29, 1911. She complained of headache, fever, and dyspnea. Her father died of tuberculosis four years previously; a brother died at the age of eight of meningitis. The patient had had measles and scarlet fever. As long as the mother could remember the patient had had a discharge from the right ear. Ten days before admission she had complained of headache and fever and had had a slight nose-bleed. Since then the child had had some fever in the evening. The days before admission she had an attack of weakness and faintness and a physician said that she had some heart trouble and should go to the hospital. When admitted she had a temperature of 101.6° F., which fell to normal during the day. The heart was not enlarged, though there was a forcible impulse in the fourth left space within the nipple line. There was a distinct diastolic murmur in the third interspace transmitted toward the apex. The spleen was readily palpable. No positive diagnosis was made, but the following were suggested: malaria, typhoid fever, tuberculosis, endocarditis. There was a moderate leucocyte count with 78 to 82 per cent. of polymorphonuclears. No malarial organisms were found. On September 5th the temperature rose to 104.4° F. On the following day a few drops of pus were removed from the attic. The patient, however, continued to run an irregular fever, hectic in type, with a rapid pulse. On September 16 the patient was examined carefully and there was no evidence of any pus or infection in the mastoid wound, nor any discharge from the ear, nor any indication of infection from the ear or mastoid. The Widal reaction was negative. On September 18 the patient had a small petechial spot in the conjunctiva of the lower lid of the left eye. There was some pain in the lower half of the abdomen, more on the left than on the right. The abdomen was held rigid. The pupils were equal, reacted normally, and there was no neck rigidity. The knee-jerks were normal and there was no Kernig sign. On September 27 the patient was restless and had considerable pain in the lower abdomen. There were a number of petechiæ over the arms and legs. The patient gradually went into coma and died on September 28. A diagnosis of malignant endocarditis was made from the presence of the heart lesion, high irregular fever, leucocytosis, petechiæ, and the presence of an unknown lesion. At autopsy the heart was found to be but little enlarged. The aortic valve contained but two cusps. Vegetations were found on the valves. There were a number of petechiæ scattered through the heart, as well as through the viscera. The upper respiratory tract looked somewhat like the eruption in measles. The right kidney contained a small anemic infarct. The aorta was smooth and free from any sign of degeneration. Just at the bifurcation there was a thrombus the size of the distal phalanx of the little finger, this rested upon the bifurcation, completely blocking the left iliac artery and partially blocking the right, and extended backward to a point just below the origin of the last lumbar artery. The left iliac artery below the thrombus was contracted down to a thin cord. This case was of unusual interest on account of the masking of the diagnosis by the presence of an ear discharge; although malignant endocarditis was suspected, the continued negative blood cultures cast an element of doubt upon the diagnosis.

Abscess of the Lung, Secondary to New Growth of the Esophagus.—Dr. ROBERT ANDERSON COOKE reported the case of a German, forty-eight years old, whose trouble began three months ago with what was believed to be an ordinary cold. The condition was not very acute. The cough and the expectoration persisted and he gradually became worse. There was no rise of temperature. Three weeks after the development of his trouble he coughed considerably, had intercostal pain which had no relation to his respirations, nor was it associated with any gastric disturbances. During six months prior to his admission to the hospital he lost fifty pounds in weight. He was admitted on June 4. The physical examination did not impress one that he had lost so many pounds in weight. He breathed rapidly, and his expectoration was very profuse and very foul and putrid. The chest examination was negative except for a little area of dullness over the posterior lower lobe. There were both crepitant and subcrepitant râles present. Corresponding to the eighth interspace were a small area of bronchial breathing and many mucous râles. The upper right quadrant was quite rigid. The patient ran a continuous temperature of about 100° F. in the morning and 101° or 102° in the afternoon, sometimes going to 103°. The pulse averaged from 100° to 110°. His breathing was from 34 to 44. The urinary examination was negative. There was a moderate leucocytosis and a slight increase in the polymorphonuclears. He expectorated from six to eight ounces of foul material. No tubercle bacilli were found and no tissue fibers. No stain was made for elastic fibers. There was no question but what they were dealing with an abscess of the lung. He was placed on a general treatment, given urotropin, placed in the open air, given the regular hospital diet and

so on. He had a moderate appetite and had no difficulty in swallowing at any time. On June 15 the chest was explored with a needle but no cavity was found. He continued to grow worse. On July 4 the chest was again explored and then he satisfied himself that he had gotten into an abscess cavity. On July 10 the patient suddenly complained of intense epigastric pain, bled from the mouth and nose, passed into collapse, and died. The autopsy revealed an abscess of the lung about 3 cm. or 4 cm. in diameter. There was also found an epithelioma of the esophagus which had given no symptoms whatsoever. There had never been any interference with swallowing. This abscess lay in apposition to the epithelioma and showed that there was a direct extension, not of the new growth but merely of the abscess cavity with its hard organized tissue around it. Death was caused by a rupture of one of the larger intercostal branches of the aorta. The rupture almost ruptured the aorta itself, only being separated from it by a thin membrane. The stomach contained about a quart of blood.

Dr. LINSLEY R. WILLIAMS reported a similar case. A man had been transferred from another hospital and entered with the diagnosis of tuberculosis. He gave a history of never having had any difficulty in swallowing until two weeks before admission or four weeks before his death. He had, however, pain in deglutition. The autopsy revealed a primary epithelioma of the lower one-third of the esophagus, which was twisted around itself. The esophagus was twice the size of the closed fist. This was another instance in which there were no suggestions of carcinoma of the esophagus at all until a short time before death.

Dr. HENRY STUART PATTERSON said that he had had a case under observation which was probably one of new growth of the lung. Autopsy was refused. The *x*-ray picture showed a round shadow with its convexity to the right of the heart shadow. The question arose whether this new growth was a secondary one, or was there an abscess of the lung resulting from a carcinomatous fistula of the esophagus. It occurred to him that the *x*-ray picture could exclude the latter. A bismuth picture was taken at the same time.

Election of Officers.—*Chairman*, Dr. Walter B. Niles; *Secretary*, Dr. Linsley R. Williams.

SECTION ON SURGERY.

Stated Meeting, Held January 5, 1912.

DR. LUCIUS W. HOTCHKISS IN THE CHAIR.

A Case of Stab Wound of the Heart.—Dr. JOHN F. ERDMANN reported this case, and presented the patient. (See MEDICAL RECORD, December 17, 1910, page 1095.)

Radiography of the Ureter.—Dr. CHARLES H. PECK reported this case and presented the radiograph. The patient was twenty-five years of age and was admitted to Roosevelt Hospital on December 11, 1911, complaining of pain in the region of the right kidney and ureter. The pain was more or less constant with exacerbations, catchy in character, and radiating downward toward the bladder at times. The pain began about three weeks before her admission and was apparently brought on by coughing during the course of an acute cold. There were no other symptoms of importance. The physical examination showed nothing abnormal except a moderate degree of tenderness over the right kidney region, and even the prolapse of the kidney was not detected by palpation. The radiographs of the kidney region were negative. The cystoscopic examination was made by Dr. E. F. Kilbane, and he reported that the bladder tolerance, trigone, mucous membrane, and ureteral orifices were all normal. The rate and character of the flow of urine from the right kidney were normal, and the catheter passed to the normal distance. The capacity of the pelvis of the kidney was 19 c.c., which was practically normal. Fifteen c.c. of a 10 per cent. solution of collargol were injected into the kidney pelvis and a radiograph was taken by Dr. Edward Leaming. The plate showed that the pelvis was normal in size and in contour, that the kidney was displaced downward, and that there was a sharp twist in the ureter about one and a half to two inches below the pelvis. Operation was performed on December 16, 1911. The kidney was prolapsed but otherwise was normal in size and appearance. The pelvis was not dilated. When the kidney was delivered, and the ureter exposed for several inches, at first nothing abnormal could be seen as the kink had evidently been straightened out by the traction used. Closer inspection, however, revealed a small tense band crossing the ureter obliquely at the site of the kink; this proved to be a blood-vessel over which the ureter hung when the kidney descended in prolapse. This band was ligated and divided. Nephrotomy was then performed and a good sized, firm ureteral catheter was passed downward to the bladder, where it was left for the purpose of splinting the ureter in a correct position after replacement of the kidney. A small cigarette drain was passed into the kidney pelvis alongside the catheter, and secured with catgut suture. Nephropexy was then performed by the Edebohls method. The ureteral catheter was left in place for five days; the wound healed promptly and convalescence had been uneventful. Urinary leakage persisted only two or three days after the removal of the drain and the patient was out of bed sixteen days after the operation. The chief interest of this case was in the collargol radiograph obtained by Drs. Kilbane and Leaming, which showed so beautifully the lesion which readily accounted for the symptoms, a lesion which could not be detected by ureteral catheterization alone, nor by radiography without collargol injection. Moreover, it was a lesion which could not readily be detected at operation, as the delivery of the kidney and traction on the ureter straightened out the kink, and the vessel crossing it was very small and might easily have been overlooked.

A Case of Ankylosis of the Jaw.—Dr. ARTHUR S. VOSBURGH presented a little girl operated on for the above condition. The patient was admitted to Bellevue Hospital last summer with the meager history of a burn on the leg a year previous. This was followed by an "abscess of the face." As this "got well" she had greater and greater difficulty in opening her mouth, and her parents brought her to the hospital for this condition. Examination on admission disclosed a complete ankylosis of the jaw. A cicatrix of almost cartilaginous hardness involving the mucous membrane of the mouth occupied the left alveolabial sulcus above and below. A portion of the cicatrix extended to the right lower alveolabial sulcus. A preliminary anesthetic was given to determine the extent of the cicatrix and whether the articulation was involved. A periosteal elevator was inserted between the cheek and the bones of the upper and lower jaws. It was thus possible to open the jaws about one-half inch. In doing this three or four teeth were dislodged and were found to be carious at their roots, the crowns being intact. It was explained to the parents that any operation undertaken for the relief of this condition would involve considerable mutilation of the face and neck. Consent having been obtained the following method was pursued: The left cheek was split to the anterior border of the masseter muscle. An effort was made to avoid the branches of the facial nerve and the course of Stenson's duct. It was impossible to make any flaps of mucous membrane as the cavity of the cheek was entirely obliterated by the cicatrical condition. A flap was dissected from the neck designed to occupy the space from the anterior border of the masseter to the angle of the mouth. Its base was over the angle of

the jaw. An elevator slipped between the parotid fascia and its base enabled the flaps to be rotated into place, with the skin side to the cavity of the mouth. Here it was sutured to the indeterminate mass of tissues left from freeing the cicatrix from each alveolabial sulcus. As the cicatrix did not involve the skin of the face, the latter was sutured in place. The object of the whole procedure was to reconstruct the mucous membrane of the mouth. A paralysis of the lower branches of the facial nerve was observed a day or two after the operation. This quickly disappeared, evidently having been caused by trauma and not by severance of nerve fibers. The first results of the operation were disappointing, as owing to pain or fear of pain the patient could only open the mouth about an inch. About a week later, under cocaine anesthesia, the base of the flap was severed, thus completing the entire turning over of the flap. The edges of the large gaping wound in the neck had been undermined and drawn together, uniting by primary union all except a small triangular area at its upper limits. At this date the patient has good use of the jaws and returns to the hospital for the closure of a minute sinus at the base of the flap, probably a salivary fistula from wounding Stenson's duct.

Dr. WALTER M. BRICKNER said that Dr. Peck's case strikingly illustrated the value of collargol pyelography in patients with renal colic where no calculi or other cause had been demonstrated. Had the blood-vessel described by Dr Peck as causing the kink in the ureter any relation to the aberrant renal vessel described by the Mayos as a cause of hydronephrosis by constricting the ureter? They recommended a division of the artery as a means of curing hydronephrosis. In one case in which this was done Dr Brickner had seen this cause a complete slough of the lower end of the kidney because of its separation from its blood supply; nephrectomy became necessary. He asked Dr. Peck where the vessel ran to and where it ran from. Did this vessel rise from the renal artery or not? With regard to the introduction of the ureteral catheter during the postoperative treatment in order to keep the ureter straight, he kept a catheter in the bladder without any fear of infection until a year ago, when he had an uncomfortable experience. In performing a hysterectomy for large fibroids of the uterus he punctured the bladder; he sewed up the opening made in this viscus and, as a precaution, left a catheter in place for a few days. It was not really necessary and he was sorry he did so for an ascending pyelonephritis followed. One kidney became infected with multiple abscesses and the patient ultimately died. In the corresponding ureter, just below the pelvis, there was found at autopsy a fibroma entirely within the walls of the ureter which probably interfered with free drainage from the kidney pelvis.

Dr. W. H. LUCKETT reported a case of intermittent hydronephrosis of the left kidney. The patient had a tumor the size of one's head in the region of the left kidney that had in the last two years been appearing about every two weeks, lasting two weeks, then disappearing. The left ureter was catheterized; the pelvis accommodated 3¼ ounces of collargol. A fine *x*-ray picture by Dr. Stewart showed the dilated pelvis. He could not tell from the picture where this ureter originated. The pelvis was round and globular the calices had disappeared. At operation this kidney was delivered; a transverse incision was made in the anterior surface of the pelvis and the ureter exposed; a valve-like flap was found at the ureteral opening; the ureter left the pelvis laterally and obliquely from the anterior surface of the pelvis. The flap was split and sutured with three sutures to hold it open. The transverse incision in the pelvis was three and one-half inches long and was sutured in an opposite direction in such a manner as to lower the ureter opening. It was very difficult to catheterize this patient. One could locate a little tumor which was just above the ureteral orifice in the bladder; it appeared to be about one-quarter by one-eighth inch in size. It would appear and disappear about every ten seconds. There was a sort of valve-like action or stricture which had in all probability something to do with this obstruction at the uretheral orifice. It was hard to believe that the pelvis could be so dilated as to accommodate so much urine from such an obstruction at the ureteral opening in the bladder, and admitting the presence of this stricture it seemed that the valve-like flap in the pelvis was the chief etiological factor.

Technique of Heart Suture.—Dr. EUGENE H. POOL read this paper and made the following summary: (1) Careful preparation of the operative field was essential since many cases which had survived shock and hemorrhage had died later as a result of infection. (2) The anesthesia should consist in the sparing administration of a general anesthetic, preferably ether, when the patient showed signs of sensibility. (3) It was important to recognize that in a large proportion of heart wounds the pleura was opened and that an extrapleural cardiorrhaphy was rarely possible. (4) Differential pressure offered marked advantages chiefly by eliminating the dangers of immediate and minimizing the dangers of late pneumothorax. Its use expedited the operation by allowing a free transpleural exposure. But prior to the control of bleeding from the heart wound, positive pressure should be used with great care because it might increase the hemorrhage. (5) (*a*) A transpleural exposure with long intercostal incision was ordinarily the best because it afforded free exposure of the heart, could be applied much more quickly than other procedures, and caused less hemorrhage. This exposure should be employed when differential pressure was used, when speed was important, or when pneumothorax was present. (*b*) An effort to do an extrapleural operation was warranted in exceptional cases. These indications were: differential pressure not available, pneumothorax not present, no injury to pleura such as would render the effort useless, adequate assistance and relatively good condition of the patient. Under these conditions the flap with pedicle outward, according to Kocher, appropriately modified, was favorable. (*c*) In some cases in which the diagnosis was in doubt extrapleural exploratory pericardiotomy might be performed by resection of the sixth costal cartilage as in the primary incision of Kocher's flap operation. (6) Fine vaselined silk on a curved intestinal needle was the best material for heart suture. (7) The pericardium should be closed with interrupted catgut sutures. (8) Pericardial drainage might be dispensed with in some cases when there was short exposure and little trauma. A drain should enter the pericardium to a slight extent when the nature of the wound rendered infection probable. But in doubtful cases it was best to insert a drain down to but not into the pericardial wound, a small part of which should be left unsutured. In this an exit was provided for the large accumulation of serum which was likely to occur as the result of traumatic pericarditis, and no irritation of the pericardium was caused by the presence of the drain. (9) Pleural drainage was a prophylactic step which was often unnecessary and likely to be harmful. Unless there was a strong probability of infection it was better to delay drainage until infection had occurred and then do a secondary thoracotomy.

Radiographs Showing Adhesions Obstructing the Transverse Colon.—Dr. SINCLAIR TOUSEY presented this radiograph. The patient was 41 years of age. She was referred to Dr. Robert Coleman Kemp, the gastroenterologist, and Dr. Parker Syms, the surgeon, with a history of having had an amputation of the cervix 18 years ago, hysterectomy 13 years ago, and an operation for adhesions and removal of the appendix 7 years ago. Subsequent to the last operation she had suffered from constipation and prolapsus ani to such an extent as to suggest a

ink at the sigmoid or an invagination into the rectum. Dr. Tousey was asked to make a radiograph to determine the nature and seat of the obstruction. The stomach and intestines were empty and an enema was given which filled the rectum and large intestine with an opaque emulsion of bismuth oxychloride, 2 ounces, and white bole, ½ pound, in water, 2 pints. This was sufficient for one injection per rectum. The patient lay supine upon the plate and an intensifying screen was used. The exposure lasted 30 seconds. The radiograph showed no abnormality except a strikingly empty part of the transverse colon where the latter crossed the spine. This meant that a certain portion of the transverse colon was permeable but subject to such pressure as not to be distended with the bismuth mixture. It did not seem probable that this pressure could be due to a large enough tumor without the latter giving other signs. Another possibility to be considered was that the pressure was due to the convexity of the spine, but no compression was applied over the abdomen and no such appearance had been noted in other cases. The diagnosis became narrowed down to pressure by a band of adhesions. Dr. Syms performed a laparotomy so as to expose this portion of the intestine instead of the lowest part as had been anticipated. He found an area of the omentum three inches wide bound down and firmly adherent to the transverse colon for about two-thirds of the circumference of the gut. This caused both compression and angulation, which were relieved by separating the adhesions. The patient made a good recovery and was now having movements without a cathartic. He had brought two other radiographs of interest in this connection. One was of a man who was referred to him by Dr. Kemp with gastrosuccorrhea as the principal symptom. The stomach was always found full of gastric juice. The x-ray showed that the bismuth meal passed through the stomach and small intestine in a normal manner but that a splotch of bismuth remained adherent after the rest of the stomach was empty. This indicated an ulcerated area near the œsophagus which had not secreted enough pus to show in the stomach analyses yet still was a constant source of irritation. This had been accompanied by sick headaches which had been only temporarily relieved by an operation upon the gall-bladder and by fasting and catharsis. The stomach would frequently fill up with bile. Acting upon this diagnosis the patient had been put upon a bismuth treatment for gastric ulcer and Dr. Kemp reported the greatest improvement. Another radiograph was of a man, aged 58, also referred by Dr. Kemp. He had had a weak stomach all his life but became worse two or three years ago and lost 25 pounds. Food was found in the stomach seven to 18 hours after taking. After fasting and purgation, a bismuth meal was given consisting of 1 ounce bismuth oxychloride, a dish of mashed potato, and a glass and a half of water. A fluoroscopic examination made with the patient standing up showed the bismuth meal a shapeless mass, a hand's breadth below the umbilicus. Radiographs made 20 minutes and 6 hours after ingestion showed the stomach vertical and confined to the left side of the median line and extending below the level of the umbilicus. The second radiograph showed most of the bismuth still in the stomach, none in the duodenum but some in the ileum. The radiological diagnosis was pyloric obstruction, possibly cancerous. An exploratory operation seemed to be urgently required. Dr. Kemp reported that there were two or three old ulcers of the stomach and duodenum, all of which had perforated. Leakage was prevented by adhesions to omentum and pancreas, but these adhesions had dragged the stomach down and obstructed the pylorus. The operation of separating these adhesions was a severe one and the patient died.

Resection of Stomach in a Dog with the Help of the Surgical Stitching Machine (Heultl).—Dr. WILLY MEYER said a few weeks previous he had attended a meeting of medical men where this new surgical stitching machine was demonstrated and those present were asked to get and try it. The gentleman who brought it stated that it had been used in at least fifty cases in Budapest, Hungary; they were all human beings and the results were excellent, only two or three patients having died after the operation. Dr. Meyer said he had a case of cancer of the stomach, with obstruction at the pylorus, the patient being reduced to 85 pounds in weight, and he was tempted to use this machine because of the necessity of saving every minute of time. But he concluded to try it first on a dog, which he did, and the results obtained were shown by him. The instrument was rather a cumbersome one and consisted of two large jaws which were closed by a clamp. The arrangement was such that the turning of a crank five times introduced four rows of sutures, a double line of catgut. This was a very ingenious way of introducing four rows of sutures by the mere turning of a crank handle five times. After all he believed that surgeons would still adhere to the needle and thread and not resort to this new method. One obstacle to its use was the price, $300. It was, however, an instrument about which it was well worth knowing. The beautiful specimen shown was mounted by Dr. Sondern. It was claimed that in the use of this instrument there would be a saving of at least fifteen or twenty minutes.

Apparatus for Intratracheal Insufflation Anesthesia.—Dr. H. H. JANEWAY demonstrated this apparatus.

A New Apparatus for Administering and Warming General Anesthetics, Methods of Administration and Special Advantages.—Dr. RAYMOND C. COBURN described and illustrated this apparatus which was designed primarily for the administration of nitrous oxide and oxygen; the chief aim was simplicity, utility, and portability. He claimed to have perfected two methods of administration, the closed drop method and the warm vapor method. A light stand was provided for holding two cylinders, each of gas and oxygen. Special fittings for connecting with large cylinders might be inserted in the cylinder yokes instead of two of the small cylinders. The opening of the anesthetic chamber was quite large and loosely filled with coarse gauze. To the top of this chamber was attached an anesthetic cup, which had a needle-point valve controlling the flow of the liquid anesthetic to the chamber containing the gauze. As the anesthetic dropped from the cup upon the gauze it could be plainly seen and the amount accurately regulated by the needle-point valve. The liquid anesthetic was added by the mechanical drop method, thus insuring it to be regular and constant, and at the same time the flow was in sight and under complete control of the anesthetist. The other end of the chamber was attached to the inhaler, which had an expiratory orifice which was open when the exhalations were allowed to escape and closed when there was rebreathing. The inhaler carried an inner tube; here there were two light and delicately constructed valves, so arranged that they were thrown out of action when there was rebreathing, and when the exhalations were to escape one valve prevented breathing back into the bag during expiration, and the other prevented any air from being inspired through the expiratory orifice during inspiration, the change from one form to the other being easily and quickly made by simply turning the knob through an angle of 90 degrees. The expiratory orifice always directed the exhalations away from the patient's face and field of operation. To the other end of the inhaler was attached the face mask, which fitted the face accurately; it was quite necessary that this mask should form an air-tight fitting of the patient's face. A small and light electric heater might be connected to any lamp socket and it

thoroughly warmed all the anesthetic vapor. As the chamber and heater were attached to the inhaler, the heat was conducted along the metal connections so that the anesthetic vapor had no chance whatever to cool and consequently could be delivered to the patient at practically body temperature. Its special advantages were: (1) Simplicity. The design, construction, and operation were reduced to the basic principles of simplicity. (2) Utility. Each and every one of the inhalation anesthetics could be administered by all the different methods in common usage. It could be easily, quickly, and thoroughly sterilized, and above all else it was practical. (3) Portability. Being complete in design, light in construction, and easily assembled the entire apparatus, together with sufficient nitrous oxide and oxygen for two hours' anesthesia, could be readily carried in an ordinary handbag. (4) Economy. The whole apparatus was not expensive. It covered the entire field for general anesthetics by the oral-nasal route, and no other equipment was needed for the highly specialized methods. It saved one-third of the cost of all anesthetics administered by the open method and reduced to an absolute minimum the cost of the anesthetic by the rebreathing method. In closing Dr. Coburn said that for nitrous oxide administration it furnished a light and compact stand for holding the proper number of cylinders, and placed the rubber bag close to the patient's face. The stand was absolutely rigid with slip connections. It afforded practical means for administering ether by a new method, the closed drop method, which was the logical and scientific complement of the open drop method. For ethyl chloride administration by the open method it insured that the anesthetic would always be completely vaporized and diluted before being inhaled. It thoroughly warmed the vapor of ether by the open drop method. It always showed whether the patient was actually breathing, no matter what anesthetic was used or method employed. It warmed the vapor of all anesthetics to practically body temperature at the time it was inhaled. It reduced the administration of ether to a scientific basis, semi-open or closed methods, and maintained with absolute constancy. In the open method it prevented the waste of the anesthetic from vaporization by the expirations. It afforded the utmost possible conservation of the patient's energy.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

Delaware Medical Examining Board.

December 12, 13, and 14, 1911.

ANATOMY.

1. Give shape, size, and number of segments forming os hyoides.
2. Give shape, location, and articulations of sphenoid bone.
3. Give origin, course, and insertion of pectoralis major muscle.
4. Give origin, length, and insertion of sternothyroid muscle.
5. Origin, course, and distribution of left subclavian artery.
6. Origin and distribution of innominate artery.
7. Origin and distribution of superior laryngeal nerve.
8. Origin and distribution of pneumogastric nerve.
9. Explain origin, course, and distribution of right internal jugular vein.
10. Describe formation and structure of superficial cervical lymphatic glands.

PHYSIOLOGY.

1. What four chemical elements enter most largely into the composition of animal bodies?
2. Give an outline of the circulation of the blood in the human body (omitting portal circulation).
3. Discuss the function of the spleen.
4. What is accomplished by pulmonary respiration?
5. Describe the gastric juice.
6. Discuss the function of the kidneys.
7. What is meant by the term metabolism?
8. Name the types of muscle tissue and outline the part played by each.
9. What is meant by a reflex movement or action?
10. Trace the optic nerve from its origin to its distribution and state to what forms of stimuli it will respond.

CHEMISTRY.

1. To what group of metals does potassium belong, where found, and is it indispensable to the animal organism, and why?
2. Does ammonia belong to the same group as potassium, and how is it used in making ice?
3. To what group of metals does magnesium sulphate belong, where found in nature, and how prepared?
4. How are the effervescing solutions made more palatable?
5. What is the difference between hard and soft water? State what takes place chemically on boiling hard water.
6. What are amylopsin and trypsin?
7. What are benzine and toluol, giving symbols?
8. From what are the phenol acids derived?
9. What is uric acid, and where found in the human system? Give its chemical symbols.
10. How are the two chief bile pigments formed?

MATERIA MEDICA.

1. Name the officinal liquid preparations.
2. Name and give the dose of eight of the most important preparations of iron.
3. Name the digestive ferments and define the action of any two of them.
4. What are the physiological effects of phosphorus?
5. Name the incompatibles of cinchona and its alkaloids.
6. What are alteratives? Mention some drugs of this class.
7. How is iodine obtained? Make a list of the iodide salts.
8. Name the preparations and doses of belladonna.
9. Define the physiological actions of scilla.
10. Name one cardiac stimulant and one cardiac sedative, with preparations and doses of each.

THERAPEUTICS.

1. What is serum therapy? Mention the serums that are official.
2. What are the therapeutic uses of the simple bitters?
3. Mention the more important medical uses of the preparations of mercury.
4. Define fully the therapeutic uses of arsenic.
5. What are the medical uses of the phosphates and the hypophosphites?
6. Name the local anesthetics and tell something of their use.
7. Mention conditions which would influence the dose of drugs when prescribing.
8. Describe the routine treatment in a case of poisoning by free iodine.
9. What are the medical uses of the nitrites?
10. In the practice of our profession what uses can we make of adrenalin or the suprarenal gland?

PATHOLOGY.

1. Name the morphological types of pathogenic bacteria and give an example of each.
2. Describe the *Bacillus tetani*.
3. How does an antitoxin differ from a vaccine?
4. Differentiate between fatty infiltration and fatty degeneration.
5. Describe the process of repair in a superficial uninfected wound.
6. How would you proceed in securing and preparing a specimen of blood to be examined for the malarial organism?
7. Describe a section from a so-called fibroid tumor of the uterus.
8. Describe a typical specimen of urine from a case of diabetes mellitus.
9. Differentiate pathologically between bronchopneumonia and lobar pneumonia.
10. Discuss the diagnostic value of the Wassermann reaction.

PRACTICE OF MEDICINE.

1. Give symptoms, including physical signs, of acute lobar pneumonia.
2. Give your treatment in full of bronchopneumonia in children.

3. Differentiate diabetes mellitus from diabetes insipidus. Give treatment of former.
4. Give symptoms and treatment of chorea.
5. Diagnose follicular tonsillitis from diphtheria. Give treatment of latter.
6. What is meant by cardiac compensation? Give illustration.
7. Etiology and symptoms of cirrhosis of the liver?
8. Symptoms and treatment of acute nephritis?
9. What is uremia? Give symptoms and treatment.
10. Give clinical history and treatment of acute catarrhal enteritis.

OBSTETRICS.

1. Name the contents of a well-equipped obstetric outfit.
2. Describe the physiological process in the impregnation of the human ovum.
3. In what manner does the female pelvis differ from that of the male? Name the pelvic bones.
4. Name five anomalies of the umbilical cord and the possible effect of each.
5. Into how many stages is labor divided? Define each stage.
6. Define (*a*) abortion, (*b*) miscarriage, (*c*) premature labor.
7. Give the mechanism of labor in face presentations.
8. What are the causes, modes of prevention, and treatment of rupture of the perineum?
9. Name the possible sources of puerperal hemorrhage and treatment of each.
10. What directions should be given as to the hygiene and management of the newly born?

SURGERY.

1. Explain technique of laryngotracheotomy. Give physical conditions that make the operation necessary.
2. Give symptoms and treatment of fracture at acromion end of clavicle.
3. Differentiate tuberculous and syphilitic synovitis.
4. Explain method of reduction of dislocation of the several forms of displacement of the head of the humerus.
5. Give three popular methods of amputation of foot.
6. What are the structural changes that induce strangulated inguinal hernia? Give method of operating for its relief.
7. Give causes and explain treatment of lacrymal abscess.
8. Differentiate congestion and compression of brain.
9. Explain method of operating for radical relief of inguinal hernia.
10. Give etiology, diagnosis, and treatment of strumous synovitis.

HYGIENE.

1. What do you understand by the predisposing and exciting causes of disease?
2. Name some of the principal animal and vegetable parasites which produce disease.
3. What are connate conditions? Define temperament, idiosyncrasy, and diathesis.
4. Define ventilation, state, in cubic centimeters, the quantity of air taken into the lungs by an adult person at each ordinary inspiration.
5. What method or system of removal and disposal of sewage and garbage would you recommend?
6. Name four essential alimentary principles in food, and the quantity of water required daily by an adult.
7. What meats are most easily digested, and why is the flesh of most fish white?
8. What diseases are conveyed through milk?
9. What insects convey microorganisms and disseminate disease? Give methods of preventing the action of pathogenic bacteria by means of the sera of immune animals.
10. State the value of disinfection and isolation in contagious diseases, and what disinfectants would you employ?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

DELAWARE MEDICAL EXAMINING BOARD.

December 12, 13, *and* 14, 1911.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 145; or Gray's "Anatomy" (1910), page 153.
2. The sphenoid bone is in shape like a bat with extended wings; it is situated at the anterior part of the base of the skull; it articulates with:—two malar, two palate, vomer, occipital, two parietal, frontal, two temporal, and ethmoid bones.
3. See Cunningham's "Anatomy" (1909), page 323; or Gray's "Anatomy" (1910), page 457.
4. See Cunningham's "Anatomy" (1909), page 406; or Gray's "Anatomy" (1910), page 387.
5. See Cunningham's "Anatomy" (1909), page 822; or Gray's "Anatomy" (1910), page 627.
6. See Cunningham's "Anatomy" (1909), page 801; or Gray's "Anatomy" (1910), page 585.
7. See Cunningham's "Anatomy" (1909), page 692; or Gray's "Anatomy" (1910), page 1009.
8. See Cunningham's "Anatomy" (1909), page 690; or Gray's "Anatomy" (1910), page 1006.
9. See Cunningham's "Anatomy" (1909), page 875; or Gray's "Anatomy" (1910), page 716.
10. See Cunningham's "Anatomy" (1909), page 911; or Gray's "Anatomy" (1910), page 780.

PHYSIOLOGY.

1. Carbon, hydrogen, oxygen, and nitrogen.
2. "The right auricle receives the venous blood as it returns from the tissues, and transmits it to the right ventricle. The function of the right ventricle is to pump the venous blood through the pulmonary arteries into the lung capillaries, where the venous blood becomes oxygenated. The oxygenated blood returns by the pulmonary veins to the left auricle, and the arterial blood is then received into the left ventricle. The left ventricle pumps the arterial blood through the large arteries, the small arteries, and the arterioles into the systemic capillaries. For the most part between the capillaries and the tissues is the tissue fluid, and across this the tissues acquire the oxygen from the arterial blood, and return carbon dioxide to the blood in the capillaries. The blood which leaves the tissues is venous. The venous blood returns from the capillaries through the small veins into the larger veins, and the largest veins pour the blood back into the right auricle. It will thus be seen that the right side of the heart is occupied with the pulmonary circulation, and the left side of the heart with the systemic circulation." (Lyle's *Physiology.*)
3. The *function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.
4. *Respiration* is the process by which an interchange of gases takes place in the lungs; so that oxygen is introduced and carried to the tissues, and carbon dioxide is expelled.

The changes produced in the *air* by respiration are:

	INSPIRED AIR.	EXPIRED AIR.
Oxygen	21 per cent	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	0.04 per cent	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of the body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

5. *Gastric juice* is a thin, colorless fluid; acid in reaction; specific gravity about 1002 to 1010; and containing about 1 per cent. of solids. The daily secretion amounts to 10 or 15 pints. It contains: Water, pepsin, rennin, hydrochloric acid, chlorides (of calcium, sodium, and potassium), and phosphates (of calcium, magnesium, and iron). Its function is to change proteids into proteoses and peptones, and to curdle the casein of milk; it is also slightly antiseptic, and inverts cane sugar into dextrose and levulose.

The pepsin and rennin come from the central cells in the cardiac glands and from the cells of the pyloric glands. In both of these glands the pepsin preexists as pepsinogen. The hydrochloric acid is formed by the oxyntic cells. Just how a free acid is formed from the alkaline blood and lymph is not known. It has been suggested that it may occur as follows:

(1) $2Na_2HPO_4 + 3CaCl_2 = Ca_3(PO_4)_2 + 4NaCl + 2HCl$

or (2) $Na_2HPO_4 + H_2O + CO_2 = NaHCO_3 + NaH_2PO_4$;

and then $NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl$.

6. The *functions of the kidneys* are: (1) To excrete water, urea, and other waste products; (2) to form hippuric acid; (3) to control the reaction of the urine, by forming acid sodium phosphate. The main function is the secretion of urine. The mechanism of the *secretion of*

urine by the kidneys is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also morganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules the urea and principal solids are eliminated.

7. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative or constructive (anabolism) and (2) destructive (katabolism).

8. Muscles are divided into two great classes: Voluntary and involuntary. *Voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is non-striated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated. *Voluntary* muscle is, as a rule, under the control of the will. *Involuntary* muscle performs its contractions independently of the will; it is also characterized by periods of rest and activity, or rhythmicality; it is further characterized by peristalsis.

9. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral.

10. For origin and course of optic nerve, see Cunningham's "Anatomy" (1909), page 675; or Gray's "Anatomy" (1910), pages 977 and 911. The optic nerve responds to the stimulus of waves of light falling upon the retina.

CHEMISTRY.

1. Potassium belongs to the group of alkali metals; it is found in rocks, and minerals, and in plants; it is indispensable to the animal organism, because it is a constituent of the red blood corpuscles and of other cells and tissues.

2. Ammonia is neither an element nor a metal, and so cannot belong to the same group as potassium. Under a pressure of more than six atmospheres it is condensed to the liquid used in ice machines to cause a freezing temperature by its evaporation.

3. Magnesium belongs to the alkaline earths. Magnesium sulphate is found in sea water and in the water of certain bitter mineral springs. It is prepared by the action of sulphuric acid on magnesium carbonate.

4. Effervescing solutions are made more palatable by the addition of citric and tartaric acids.

5. Hard water contains an excess of calcium and magnesium salts; soft water does not. When hard water is boiled the bicarbonates are decomposed, carbon dioxide is given off, and insoluble carbonates are precipitated.

6. Amylopsin and trypsin are ferments found in the pancreatic juice. Amylopsin converts starches into dextrin and maltose; and trypsin converts proteids into proteoses and peptones.

7. *Benzin* is a petroleum product. *Benzene* or *benzol* is an aromatic hydrocarbon with the formula C_6H_6. *Toluol* is methyl benzene, or benzene in which one atom of hydrogen has been replaced by the univalent radicle methyl; formula is $C_6H_5.CH_3$.

8. The phenol acids are derived from benzoic acid.

9. Uric acid is trioxypurin. It is found in the urine, blood, and other tissues. Its formula is $C_5H_4N_4O_3$.

10. The two chief bile pigments (bilirubin and biliverdin) are formed by the breaking up of hemoglobin.

MATERIA MEDICA.

1. The *official liquid preparations* are. Vinegars, waters, solutions, infusions, decoctions, syrups, honeys, mucilages, emulsions, mixtures, oleoresins, wines, fluidextracts, tinctures, spirits, elixirs, liniments, collodions, and glycerites.

2. Reduced iron, gr. j; ferrous carbonate, gr. iv; Basham's mixture, 3iv; syrup of ferrous iodide, ♏xv; tincture of ferric chloride, ♏viij; iron and ammonium citrate, gr. iv; ferrous sulphate, gr. iij; and ferric chloride, gr. j.

3. There are only two *official* digestive ferments, viz., pepsin and pancreatin. Trypsin is also a digestive ferment.

Pepsin is indicated as an aid to gastric digestion in gastralgia, gastric cancer and ulcer, atonic dyspepsia, and the vomiting of pregnancy.

Pancreatin is indicated as an aid to digestion, and for the predigestion of food, in convalescence, in wasting diseases, and in intestinal dyspepsia.

4. Phosphorus acts locally as an irritant; internally it is a stimulant to the nervous system and also to the bone-forming cells, a tonic, a repairer of waste, a circulatory stimulant and an aid to the formation of red blood corpuscles. It is partly oxidized into phosphorous acid or phosphoric acid, of the oxygen in the red corpuscles. In large doses it increases the urea and other nitrogenous products, raises the body temperature, diminishes the glycogen of the liver, and may cause fatty degeneration.

5. *Incompatible with cinchona and its alkaloids* are. Mineral acids, alkalies, carbonates, ferric and ferrous salts, lead acetate, lime water, magnesia, mercuric chloride, silver nitrate, tartar emetic, zinc sulphate, picric and tannic acids, borax, ichthyol, oxalic acid, salicylates, sodium phosphate.

6. *Alteratives* are drugs which, in some unknown way, alter the course of morbid conditions. *Examples:* Arsenic, antimony, sulphur, mercury, colchicum, iodine, sarsaparilla, cod liver oil, phosphorus.

7. *Iodine* is obtained from the ashes of seaweed and from the mother liquor of Chili sodium nitrate. *Iodides:* Of ammonium, potassium, sodium, strontium, lead, mercury, and zinc.

8. *Preparations and doses of belladonna:* Extract, gr. 1/5; tincture, ♏viij; fluidextract, ♏j; liniment, and plaster.

9. *Physiological action of scilla:* Expectorant, diuretic, gastrointestinal irritant, emetic, slows the heart, strengthens and slows the pulse, and raises arterial tension.

10. *Cardiac sedative*, aconite; fluidextract, ♏j; tincture, ♏x.

Cardiac stimulant, sparteine; sparteine sulphate, gr. 1/10

THERAPEUTICS.

1. *Serum therapy* is the prophylaxis and treatment of certain infectious diseases by the administration of a blood serum containing an antibody specific to the particular disease. *Official serum:* Antidiphtheritic serum.

2. *Therapeutic uses of simple bitters:* To stimulate the nerves of taste, promote appetite, increase the flow of saliva and of gastric juice, and aid digestion.

3. *Mercury* is used in syphilis, tuberculosis, tonsillitis, parotitis, irritable stomach, nausea, vomiting, dysentery, gastric ulcer, enteritis, diphtheria, cholera, iritis, biliousness, constipation; as an antiseptic, antipruritic, parasiticide; as a caustic for chancroids and venereal warts.

4. ARSENIC. *Physiological action:* Escharotic; irritant, tonic; increases cardiac action, respiratory power, intestinal secretions, and peristalsis; produces edema, itching, diarrhea, epigastric pain, irritable and feeble heart. *Therapeutic uses:* In stomach disorders, bronchial and pulmonary affections, diabetes, diarrhea, anemia, and chlorosis, chorea, malaria, and chronic skin diseases.

5. "Calcium phosphate and the hypophosphites are used with benefit in all diseases of malnutrition, and where the repair or development of the bones is required. They are particularly useful in protracted suppuration, osteomalacia, rachitis, caries, scrofulosis, chronic phthisis, and in anemia and bone-softening of lactation. The hypophosphites are much employed in nervous and general debility and in chronic lung diseases, and are supposed to act in the same manner as free phosphorus, but without irritation. They are probably converted into phosphates in the stomach, and hence may be expected to promote the growth and healing of bones, to stimulate the hepatic and intestinal secretions, and to affect the lymphatic glands and adenoid tissue. The compound syrup of the hypophosphites is an excellent remedy in acne indurata. Sodium phosphate in doses of 3j-ij thrice daily for adults (gr. x-xxx for children) is extremely useful as a laxative in conditions depending on catarrh of the bile-ducts and duodenum, as headache, jaundice, and chalky stools. Gallstones may be prevented from forming by scruple or drachm doses before meals for months at a time. It is an efficient agent in obesity, hepatic diabetes, incipient hepatic sclerosis, chronic infantile diarrhea, cerebral debility, bilious sick-headache, and the pasty, white stools of ill-conditioned children."—(Potter's *Therapeutics*, etc.)

6. *Local anesthetics:* Cocaine, eucaine, ice, ether spray, ethyl chloride, chloretone, phenol. They are used to impair the conductivity of the sensory nerves, and to depress the end organs in the skin. Their chief use is in surgery.

7. *The dosage of drugs* is influenced by: Age, sex, weight, nationality or race, disease, pain, idiosyncrasy, body temperature, drug habits, method of administration, and the cumulative action of the drug.

8. Solution of starch should be given in case of poisoning by iodine.

9. *Nitrites* are used medicinally: To lower arterial pressure; to dilate the arterioles; to relieve angina pectoris, epilepsy, eclampsia, dyspnea, chronic nephritis, and arteriosclerosis.

(1) *Adrenalin*, is used to check hemorrhages (nasal, pulmonary, gastric); also in bronchitis, edema of glottis, diabetes insipidus, congestion of lungs; as a hemostatic after operations on the nose and throat, and in coryza, laryngitis, etc.

PATHOLOGY.

1. *Morphological types of pathogenic bacteria:* (1) *Cocci*, which are round, or oval, and may appear singly, in pairs, in groups of four, in chains, or in bunches. (2) *Bacilli*, which are rod-shaped, with the longer sides parallel, and the short ends either straight, rounded, or concave. (3) *Spirilla*, which are spiral. *Examples.* (1) Gonococcus, (2) bacillus of typhoid fever, (3) spirillum of relapsing fever.

2. *The bacillus of tetanus* is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaerobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon it grows near the bottom of the tube and produces gases.

3. An *antitoxin* is a substance formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

A *vaccine* is an emulsion of dead cultures of specific bacteria.

4. In *fatty infiltration* the tissues contain fat brought from without; there is no change in the cell protoplasm, and such damage as the tissue undergoes is due to the mechanical pressure caused by the fat.

In *fatty degeneration* the cell protoplasm undergoes change; the fat is in the cells, and not between them.

5. See Rose and Carless' "Surgery" (1911), pages 253 and 249; or Da Costa's "Surgery" (1908), page 110.

6. *In examining for malaria:* "Prepare some perfectly clean and very thin cover slips, and remove all traces of grease. Cleanse the skin of the finger-tip or ear with soap and water, and then with alcohol and ether. Make a *small prick* in the skin. Wipe away the first drop of blood, leaving a perfectly dry surface, so that subsequent drops will not run. Squeeze out a tiny drop about the size of a large pin's head. Touch the apex of this drop with the center of a cover glass, and immediately drop it, face downward, on a perfectly clean slide. Make several such preparations, and reject all those in which rouleaux are present. It is absolutely essential that the red corpuscles should lie flat. Examine with a 1/12 immersion lens and rather feeble illumination. Look in the red corpuscles for the presence of small black specks, often rod-like and showing slow movements of translation. These are surrounded by clear areas. One may also see in the center of some of the red cells clear ameboid areas which show no pigment. Rosette forms may also be visible. These forms of the parasite are always present in cases of malaria which have not had quinine. Other varieties are only met with in some chronic cases. Of these there are two chief forms: (1) The crescentic, (2) the flagellated. These are easily recognized. The crescentic bodies are highly refractile, rather longer than a red blood corpuscle, and about 2μ in diameter. Particles of pigment may be recognized in the parasite and also in some of the ordinary leucocytes."—(Hutchinson and Rainy.)

7. Uterine fibroids "present themselves in the form of rounded and usually well-circumscribed masses, from the size of a grape seed to that of tumors weighing forty or fifty pounds. They are generally multiple; are very hard; and on section have the appearance of concentric or irregular lamellæ. Microscopically the tumor is composed of smooth muscle-fibers and of fibrous tissue arranged in bundles or layers running in various directions. The muscle-fibers are frequently found arranged concentrically about small blood-vessels, and in some instances the vessels are telangiectatic."—(Stengel's *Pathology.*)

8. See French's "Practice of Medicine" (1910), page 971; or Osler's "Practice of Medicine" (1909), page 415.

9. See French's "Practice of Medicine" (1910), pages 154 and 687; or Osler's "Practice of Medicine" (1909), pages 170 and 622.

10. The *diagnostic value of the Wassermann reaction* is well summed up in a recent number of *Progressive Medicine:*

(1) The test should only be used in the light of the clinical findings. 2. Its real value depends upon its interpretation and a knowledge of its limitations. (3) The reaction is not specific in the ordinarily accepted sense of the term, but depends upon biochemical phenomena as yet not understood. (4) While a positive reaction means infection with syphilis in 99 per cent. of the cases, it cannot be regarded as conclusive without knowing the character of the work done by the serologist. The test is so delicate and its technique must be so rigorously carried out that one examination should not be relied upon in doubtful cases. (5) A negative reaction has even less weight, and should be repeated and unimpeachable to be accepted. (6) Its chief diagnostic value is in obscure cases; as an indication as to therapy it is valuable, but less so than other symptoms. (7) The test can never supplant competent and exhaustive clinical observation, but can aid it greatly. (8) In case of difference between definite clinical signs and the serum test the former has the preponderating weight as evidence.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), page 156; or Osler's "Practice of Medicine" (1909), page 172.

2. See French's "Practice of Medicine" (1910), page 690; or Osler's "Practice of Medicine" (1909), page 626.

3. See French's "Practice of Medicine" (1910), pages 971, 973, 978, and 974; or Osler's "Practice of Medicine" (1909), pages 419, 425, and 420.

4. See French's "Practice of Medicine" (1910), pages 1154 and 1150; or Osler's "Practice of Medicine" (1909), pages 1048 and 1052.

5. In *diphtheria* the onset is more gradual; the temperature rises to about 102° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium and are easily brushed away; Klebs-Loeffler bacilli are never found.

For treatment of diphtheria, see French's "Practice of Medicine" (1910), page 195; or Osler's "Practice of Medicine" (1909), page 207.

6. *Compensation.*—"The alteration in the systemic blood supply caused by the valvular defects of chronic endocardial inflammation are such that, if continued, the integrity of the body is threatened. To overcome the impaired functions of the valves and to maintain the general circulation, the heart increases in size and strength (*compensatory hypertrophy*). The period in which this occurs is called the *period of compensation;* its duration is indefinite. It may be recognized by the physical signs of valvular disease without any symptoms of disturbed circulation. Anything which disturbs the equilibrium as it now exists, such as acute diseases and excessive work, leads to *ruptured compensation*, a condition attended by cyanosis, dyspnea, edema, gastric, hepatic, and renal disturbances, and often death. The object in the treatment of all forms of chronic valvulitis is to obtain compensation and to prevent its failure or rupture."—(Hughes' *Practice of Medicine.*)

7. See French's "Practice of Medicine" (1910), pages 842 and 845; or Osler's "Practice of Medicine" (1909), page 556.

9. See French's "Practice of Medicine" (1910), pages 905 and 909; or Osler's "Practice of Medicine" (1909), pages 683 and 702.

10. See French's "Practice of Medicine" (1910), pages 790 and 791; or Osler's "Practice of Medicine" (1909), pages 498 and 503.

OBSTETRICS.

1. The contents of the obstetrical bag will vary with the requirements and experience of its owner, and the preparations already made by the patient. In any case the following articles should be taken by the accoucheur to a confinement: Tablets of bichloride of mercury, or some other material for making antiseptic solution; forceps; ether or chloroform, with inhaler or mask; fluidextract of ergot; hypodermic syringe, with tablets of strychnine, morphine, etc.; needles, sutures, and needle holder; nail-brush and nail-cleaner; umbilical scissors; carbolized vaseline; stethoscope; male catheter (rubber); a 1 per cent. solution of nitrate of silver, with eye dropper.

In addition to the above some would also include: A sterile apron or suit; a Kelly pad; solution of cocaine, soap, boric acid, and gauze, all sterilized, absorbent cotton, iodoform gauze, chloral hydrate; dilators, and other instruments.

A bag or grip made of canvas, or a metal case covered with canvas, is better than a leather bag, as the former can be sterilized.

2. See Jellett's "Midwifery" (1910), page 70; or Hirst's "Obstetrics" (1909), pages 71 to 74.

3. The chief differences between the male and female pelvis are thus tabulated in *Morris's Anatomy*:

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischio-pubic rami more everted.	Margins of ischio-pubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater.

The *pelvic bones* are: Two ossa innominata (made up of ilium, ischium, and pubes), and the sacrum and coccyx.

4. See Jellett's "Midwifery" (1910), page 529; or Hirst's "Obstetrics" (1909), page 138.

5. Labor is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with the complete dilatation of the os uteri, and ends with the birth of the child. The *third stage* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

6. *Abortion* is delivery of the product of conception before the twelfth week.

Miscarriage is delivery of the product of conception between the twelfth and twenty-eighth weeks.

Premature birth is delivery of the fetus between the twenty-eighth week and full term.

7. See Jellett's "Midwifery" (1910), page 372; or Hirst's "Obstetrics" (1909), page 410.

8. See Jellett's "Midwifery" (1910), pages 919 and 344; or Hirst's "Obstetrics" (1909), pages 334 and 609.

9. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of the hemorrhages in question:

A. Hemorrhages of Pregnacy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of Labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the Puerperium: Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

For treatment see index in Jellett's "Midwifery" or Hirst's "Obstetrics," under heading "Hæmorrhage," or "Hemorrhage."

10. See Jellett's "Midwifery" (1910), page 1143; or Hirst's "Obstetrics" (1909), page 928.

SURGERY.

1. See Rose and Carless' "Surgery" (1910), page 922; or Da Costa's "Surgery" (1908), page 771.

2. See Rose and Carless' "Surgery" (1911), page 494; or Da Costa's "Surgery" (1908), page 484.

3. For *tuberculous synovitis* see Rose and Carless' "Surgery" (1911), pages 652 and 654; or Da Costa's "Surgery" (1908), pages 550 and 548.

Syphilitic synovitis: "In the secondary stage, during the prevalence of skin eruptions, ulcers of the tonsils, plastic, iritis, etc., one or more of the joints (most usually a single articulation, and that either the knee or the elbow) may be the seat of an affection consisting of gummatous induration of the subsynovial tissue and effusion into the synovial cavity. In these cases thickening of the periarticular tissues in the form of ill-defined indurations, or sometimes of distinct nodular deposits, may sometimes be detected. In their general character, however, these affections present little to distinguish them from ordinary chronic synovitis, and their true nature is suggested only by their origin apart from the common causes of synovitis, and the fact that the subjects of them have had, or are still suffering from, other forms of syphilitic disease. Their main features are their persistency and their strong tendency to relapse. Pain, heat, and stiffness are usually but little marked."—(Treves' *Manual of Surgery.*)

4. See Rose and Carless' "Surgery" (1911), page 921, or Da Costa's "Surgery" (1908), page 590.

5. See Rose and Carless' "Surgery" (1911), page 1339, or Da Costa's "Surgery" (1908), page 1215.

6. See Rose and Carless' "Surgery" (1911), pages 1115 and 1121; or Da Costa's "Surgery" (1908), pages 992 and 995.

7. LACRYMAL ABSCESS. "*Causes.* Chronic dacryocystitis is always the forerunner of abscess, infection is the immediate cause. *Treatment* consists in treating the dacryocystitis. When the abscess is forming hot fomentations or poultices are indicated. When the tumor softens it should be promptly and freely incised through the skin and the cavity syringed and packed with gauze. The wound is then dressed daily on general surgical principles. If excessive granulations form, they may be treated by scraping or by nitrate of silver stick. When all reaction has subsided the canaliculus should be slit and the nasal duct probed if possible, in order to prevent recurrence, which is liable to take place."—(Alling's *Diseases of the Eye.*)

8.

CONCUSSION OF THE BRAIN.	COMPRESSION OF THE BRAIN.
Unconsciousness is incomplete; patient can be made to answer, though it may be briefly, and in simple words.	Complete unconsciousness; may scream into patient's ear at the top of the voice, but will receive no answer.
Special senses, though greatly blunted, are not abolished.	Special senses entirely suspended.
Power of movement not destroyed; if the position of a limb be changed the patient will resist or bring it immediately into the original position.	Complete or partial paralysis; in most cases hemiplegia.
Respiration is quiet and feeble.	Respiration full and noisy.
Pulse feeble, frequent, and intermittent.	Pulse full and slow, and sometimes laboring.
The stomach sickens; and rejects its contents.	The stomach is insensible to any impression; no nausea or vomiting.
The feces may be discharged incontinently, as may also the urine, though not usually.	Bowels are torpid, and the bladder incapable of emptying itself, though the urine may escape by overflow.
Deglutition little impaired.	Deglutition difficult or impossible.
Pupils variable, though generally contracted; the eyelids somewhat open.	Pupils variable, though generally much dilated, and the eyelids closed.
Temperature of the body less than natural.	Temperature almost natural, a little below the normal standard.

—(Treves' *Manual of Surgery.*)

9. See Rose and Carless' "Surgery" (1911), page 1100; or Da Costa's "Surgery" (1908), page 978.

10. See Rose and Carless' "Surgery" (1911), pages 652 and 654; or Da Costa's "Surgery" (1908), pages 222, 548, and 550.

HYGIENE.

1. *Predisposing cause* of disease is anything which affects the body in such a way as to render it susceptible to the action of the exciting cause.

Exciting causes are such as immediately precede and precipitate an attack of disease.

2. *Animal parasites which produce disease:* Tapeworms, trichina, echinococci, filaria, acarus; and see French's "Practice of Medicine" (1910), pages 8 and 50.

Vegetable parasites which produce diseases. All the

pathogenic bacteria (see French's "Practice of Medicine" (1910), pages 65, etc.; or Rose and Carless' "Surgery" (1911), pages 120, etc.).

3. *Connate conditions* are congenital conditions, or those which are born with a person.

Temperament: "The physical organization peculiar to the individual which influences one's metabolic processes, manner of thought and action, and general views of life."

Idiosyncrasy: "An individual mental or physical characteristic or peculiarity." Or "a susceptibility peculiar to the individual to the action of certain drugs, articles of diet, etc."

Diathesis: "A constitutional state predisposing to any disease or group of diseases."—(Stedman's *Medical Dictionary.*)

4. *Ventilation* is a process by which a constant supply of fresh air is furnished and impure air is banished. The quantity of air taken into the lungs by an adult at each ordinary inspiration is about 350 to 500 cubic centimeters.

5. For *garbage* the cremation system is to be recommended; for *sewage disposal* either the water system or the biological process.

6. *Four essential alimentary principles in food:* Proteids, fats, carbohydrates, and salts. The quantity of water required daily by an adult is about four pints, in addition to the fluid contained in solid foods.

7. *Meats most easily digested* are: Oysters, soft-cooked eggs, sweetbread, white fish, chicken, lean roast beef, mutton.

The flesh of most fish is white because of the deficiency of hemoglobin and also of muscle pigment in fish.

8. *Diseases conveyed through milk:* Tuberculosis, typhoid, cholera, diphtheria, scarlet fever, measles, gastro-intestinal disturbances.

9. *Insects which can disseminate diseases* Flies, fleas, mosquitos, ticks, bugs.

"Serum-therapy proper is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a serum, as the antibodies invariably are. Pfergey classifies these agents as follows:

Toxins: Including tuberculin and other bacterial products employed for immunizing purposes. The attenuated virus of rabies and the toxins of streptococci, *Bacillus prodigiosus, Bacillus mallei, Bacillus lepræ*, and the cholera spirillum have been used for their respective diseases.

Antitoxic sera: Including those of diphtheria and tetanus, the only ones in general use; though antitoxins for cholera, typhoid, tuberculosis, and other diseases have been used with more or less benefit.

Bactericidal immune sera: Including those for typhoid, dysentery, tuberculosis, and cholera.

Immune but not bactericidal: Including the anti-pneumococcus, anti-streptococcus, and anti-staphylococcus sera.

This separation of the products of immunity is wholly artificial, and it may be that the sera act upon the toxins or upon the microorganisms, or upon both."—(Potter's *Materia Medica*, etc.)

And see French's "Practice of Medicine" (1910), pages 60 to 62; or Rose and Carless' "Surgery" (1911), page 20

10. Disinfection and isolation, if properly carried out, effectually prevent the spread of contagious diseases.

For *disinfection of:* (1) *Rooms*, use formaldehyde gas; (2) *clothing*, use solution of phenol (5 per cent.) for an hour, then boil for an hour; (3) *hands*, wash in soap and water and immerse in cresol or carbolic acid solution; (4) *urine and feces*, etc., should be passed into vessels containing dilute solution of formalin, of greater quantity than the expected excretion; *water closets*, dilute formalin solution

---

Pituitary Extract in Uterine Atony.—P. Kroemer reports excellent results following the use of pituitary extract in cases of labor in which the pains are weak. It is particularly valuable in cases of secondary atony in which the use of forceps has the disadvantage of favoring the continuation of this atony during the third stage of labor. Another indication for the use of this drug is as a preliminary to the performance of cesarean section, in which it markedly controls the hemorrhage.—*Zentralblatt für Gynäkologie*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended February 3, 1912.

	Cases	Deaths
Tuberculosis Pulmonalis	509	187
Diphtheria	248	22
Measles	722	11
Scarlet Fever	314	17
Smallpox	3	
Varicella	356	—
Typhoid Fever	52	13
Whooping Cough	65	8
Cerebrospinal Meningitis	4	3
Malarial Fever	—	—
Totals	2,273	267

Pathogeny and Treatment of Puerperal Eclampsia.—Bar has made a careful study of the causes of puerperal eclampsia and has arrived at the conclusion that the cause is a complex toxemia. The nature of the primary poisons is unknown. Their action causes secondary poisoning of the kidneys and liver, and the poisons thus produced add to those already acting and cause the pre-eclamptic state. Hypertension, although the immediate cause of the attacks, is not the primary causative factor. Thus there is a complex condition of toxemia of the blood serum, acting on the liver, kidneys, and brain, resulting in the phenomenon which is called puerperal eclampsia.—*Annales de Gynécologie et d'Obstetrique.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended February 2, 1912.

PATHOLOGY OF CHILL AFFECTING LOCALIZED AREAS OF THE SKIN.

BY WILLIAM HANNA THOMSON, M.D., LL.D.,

NEW YORK.

OUTSIDE of hot, moist climates, the most common cause of disease and of death is from "*catching cold.*" I first drew attention to the etiology and mechanism of this derangement in my inaugural as president of the New York Academy of Medicine in 1899. Yet it should be clearly understood that this disorder, however local, is always caused by an interference with the supply of arterial, and not of venous, blood to the part. This fact was plainly illustrated by the experiment of Overbach, who found that clamping the renal arteries for only forty minutes, so as to obstruct the flow of blood through the kidneys, was followed by albuminous urine for twenty days. We may conclude, therefore, that any local shutting off of arterial blood will promptly induce nutritive changes in the territory of that arterial distribution, which are at least analogous to the local inflammatory changes which we trace to "catching cold."

Now the arterial flow, in distinction generally from the venous, is under the regulation of a special department of the nervous system called the vasomotor nerves. This is well shown in the circulation of organs which are in symmetrical pairs, such as the two eyes, the two ears, the two hands, and the two feet, but this association does not obtain in the pair organs which are not symmetrical, such as the two lungs and the two kidneys. As to the symmetrical organs, if thermometers be placed in the axillæ, and then one thermometer be held in the left hand, while the right hand is plunged in ice water, the thermometer in the hand will fall 2° to 5° F. from arterial contraction in it, while those in the axillæ are unaffected. If the semi-translucent ears of a rabbit are held up to the light the readily seen pulsation of the arteries in one ear is found to cease at once when the other ear is pinched. Now, Overbach's experiment shows that the integrity of the tissues of a most important organ can be seriously deranged by only a very temporary withdrawal of arterial blood.

In the first place it is evident that catching cold is a very different thing from being chilled by cold; that is, from a general cooling of the body, for its most typical, as well as disastrous, results may occur while a person sits with his entire body wrapped carefully in winter clothes, but the feet meantime soaked, because he went out without his rubbers into melting snow. A cold draught on the back of the neck, however induced, may, according to individual susceptibility, cause a rhinitis, a pharyngitis, a laryngitis, a bronchitis, a pneumonia or a pleuritis. How does such purely local impression of cold occasion such widely distributed organic mischiefs? As we have remarked, we must look to the nervous system for our chief explanations. One of the first clews toward the solution of this problem was furnished by an observation of Cohnheim that, after long-continued anemia of the rabbit's ear by ligature, the blood vessels became so permeable that the restoration of the normal circulation was followed by pronounced edema of all the tissues and degenerative changes in their cells.

The principle, therefore, which we would elucidate here is that the integrity of the tissues of the body depends upon the constant circulation through them of arterial and not of venous blood. Whatever interferes with the circulation of arterial blood, though it be but a short interference, nevertheless produces serious damage to the tissues. Guided by this principle, we can understand what "catching cold" means, because every organ of the body, particularly if it be very vascular, is sensitive to the withdrawal or interference with its arterial circulation, and hence this leads us to inquire into the special mechanism of the arteries as they are governed by their vasomotor nerves.

The vasomotor nerves are but rarely acted upon by a general stimulus. Instead, such stimuli are definitely local, and yet subject to certain special laws. A study of these laws will throw much light upon our subject of "catching cold." Thus, as we have seen, the first law is illustrated by the intimate association of the vasomotor nerves supplying symmetrical organs in pairs. In the case of the hands I once made use of this property in a boy who had a pistol shot perforate the palm of his hand so as to sever the palmar arterial arch. This necessitated both the cut ends being ligated, but the hemorrhage was so troublesome that I could not secure the vessels until his other hand had been dipped in ice water, whereupon the bleeding was checked enough for me to find and tie the vessels without difficulty.

A second law is the intimate association between the vasomotor nerves of any area of the skin and those of the internal parts underneath that area. This is an important law, as it affords the explanation of a great many clinical facts. Thus, external applications, according to their nature, can produce marked stimulant or else sedative impressions upon the circulation of the parts underneath that area. This explains why poultices may so relieve pain and inflammatory irritation when applied to the skin, but likewise we find this law operative where it is important to stimulate the circulation in the stage of venous stasis.

Thus, after the subsidence of the acute stage of inflammation, we have a powerful stimulant to the internal circulation by dry cupping, which is especially useful in the bronchitis of adults. Likewise the application of a blister is actively stimulant to

the internal circulation, but should not be applied in the first stage of the inflammation.

These considerations lead directly to the whole subject of counter irritation. Thus the effect of local blood letting is always sedative. I have relieved the agonizing paroxysms of dyspnea from a thoracic aneurysm by a single leach applied at the notch of the sternum. A further illustration of this law is found in the saving of life from a quickly fatal post partum hemorrhage by dashing cold water upon the abdomen, or, better yet, by the sudden, intense cold of the ether spray. Of course, this arrest of the hemorrhage is not due to the general cooling of the parts involved, but acts only through reflex vasomotor association.

But this law has also an obverse application of much practical importance. Every internal inflammation causes a marked hyperesthesia of the skin over the inflamed organ, which leads to any irritation of it being reflected inwards to the aggravation of the inflammation. I once saw a distinguished clinician expose the chest of a woman with pericarditis for nearly an hour, so that each of his students might successively listen to the pericardial rub. The result was that in a very few hours the patient's life was despaired of from a spread of the inflammation to the whole pericardium.

Another important law is that through the vasomotor system special associations occur between certain widely separated parts of the body. All vasomotor nerves are particularly susceptible to the irritant impression of cold. This is illustrated in the case of the association existing between the feet and the circulation of the pelvic viscera. So girls can have recourse to a very dangerous suppression of the menses by putting their feet into cold water. It is surprising how long this injurious impression is retained by the pelvic nerves, so as to cause long-continued amenorrhea. On the other hand, I have found no agent so effective in restoring the function of menstruation as that of dry (not moist) heat, applied for prolonged periods to the feet. Likewise, no patient with an irritable stricture of the urethra should allow his feet to get wet and cold, and the same may be said of cases of cystitis. Also due to the same vasomotor association, if profuse bleeding occurs during operations about the rectum, the hemorrhage may be largely controlled by immersing the feet in cold water.

But the vasomotor nerves of the feet form another association which is of much importance, and that is with the circulation of the pharynx and the larynx. Every one knows that getting his feet wet may quickly produce a sore throat, if not an attack of hoarseness, extending finally into bronchitis.

Still another important association is between the nerves arising at the nape of the neck and the whole arterial circulation of the head and face—in fact, we may say that at the nape of the neck is the chief executive office which presides over the whole circulation above the diaphragm, including, of course, the circulation of the mucous membranes. One domestic remedy, for example, was to check nosebleed in a child by slipping a cold key down the back of its neck. How local the primary excitation may be is shown by the results of exposing the back of the neck to a cold draught of air. The most extensive inflammation of mucous membranes may result from a prolonged exposure, though the rest of the body may be warmly clad. Nasal catarrh, or, in fact, catarrh of the whole respiratory tract, may soon follow from thus catching cold.

But a fact of the highest moment connected with catching cold is that by the local damage to an internal part the way is opened for infecting microorganisms of the most varied kind to enter the system. Many of these infecting agents may be found throughout life, occupying the mouth and throat, but doing no harm so long as the epithelium lining of the mucous membrane is intact, such as the case with the pneumococcus, and a whole host of similar and powerful infecting agents. The demonstrated seasonal relationships of pneumonia show this very clearly. These infecting microorganisms are as little able to penetrate a healthy mucous surface as the streptococci and staphylococci, which always swarm on the skin, but can do no mischief until the surgeon ventures to make an incision in it.

These vasomotor associations have their widest illustrations in the causation and course of bronchitis. Sometimes getting the feet wet begins, as we have explained, a cold which first makes the voice hoarse, and then from the larynx proceeds steadily down the trachea and larger bronchi until the smaller air tubes become involved. Oftener than that, however, the vasomotor centres at the nape of the neck set up a catarrhal inflammation of the nasal passages, and then, with this derangement in the beginning of the breathing apparatus, it progressively invades the whole respiratory tract. Yet just this sequence occurs also when this tract is directly invaded by the specific infections of influenza, measles, and whooping cough. But what we particularly wish to explain here is the mechanism of the many fatal complications of bronchitis.

We begin with the disasters which follow upon the plugging of a main bronchus by the accidental lodgment in it of a foreign body. If this be not removed, death inevitably ensues from a most disorganizing pneumonic process of the part supplied by the bronchus, in which not only are all the air vesicles wholly destroyed, which they are not in croupous pneumonia, but the interlobular, as well as the intervesicular connective framework is rapidly damaged. No ruin of pulmonary tissue compares with this for completeness.

Now, it should be borne in mind that both the larger and the smaller bronchi should never contain anything but air. Their walls are simply moistened by a bland, slightly saline fluid, and in no part of the body is the saying more true that no mucous membrane should ever secrete mucus. When, instead, its surface is coated with mucus, it is already in a morbid condition, denoting inflammation. In the bronchi this is doubly true, for secretions there, no matter how fluid, are to all intents and purposes foreign bodies, and must be got rid of. If they cannot be got rid of, the part supplied by that bronchus is subject to the same disorganization as that described following the plugging of a main bronchus. It is then that we have a localized, but ruinous bronchopneumonia, however small its area may be.

Bronchopneumonia, therefore, occurs in every disease accompanied by bronchitis whenever, as in children, the powers of expectoration are feeble, particularly in measles and whooping cough, and is the most common cause of death in all such affections. But its initial mechanical cause should not be lost sight of, the practical aim always being to make the secretions so fluid that they can easily be coughed away. In adults this is usually accomplished with ease. If the secretion, however, is very

viscid, the coughing is hard, and in chronic cases leads to emphysematous over-distention, if not rupture, of the air vesicles. In infants, as already explained, the immediate results are very serious. The small occluded bronchi now lead to the same disorganizing process in the little lobules supplied by the bronchus, which occurs as the result above described accompanying occlusion of a main bronchus. Scattered pneumonic processes are therefore found through both lungs, for bronchitis, unlike croupous pneumonia, is a bilateral affection. In some cases, however, the plug in a small bronchus may act as a valve, interfering with the inspiration, but not with the expiration, thus leading to atelactasis of the lobule, so that in bronchopneumonia we find both pneumonic consolidation of lobules along with collapsed lobules, either condition, of course, equally interfering with the breathing. In infants, therefore, this whole process leads to most distressing efforts to get air. The little patients toss from side to side in their vain endeavors to breathe until signs of carbonic acid poisoning show the last effects of gradual suffocation; but we meet with practically the same conditions in aged patients from their feeble powers to expectorate. Remembering, however, the purely mechanical operation of their respiratory obstruction, I once had an old lady eighty-four years old, mother of a prominent New York judge, raised feet upwards by her nurses, while her head touched the floor, and while in this position I assisted her expectoration by pressure on the sides of the thorax during expiration. She thus got rid of large quantities of mucus, and was soon restored to bed quite comfortable, ultimately recovering.

In no disorder of the lungs does the morbid condition so facilitate infection by every variety of microorganism, including tuberculosis, a not uncommon sequel, especially after measles.

Treatment.—The various conditions above described afford many indications for treatment. Thus chronic nasal catarrhs point to a weakened susceptibility to the vasomotor centres at the nape of the neck. Now nothing so restores the tone of these weakened centres as cold properly applied. Thus a cold bath or shower bath invigorates the circulation, provided always that the reaction from the impression of cold is complete, but if no, or equally imperfect reaction occurs, the patient is worse off than ever; hence chronic nasal catarrhs are best treated by sudden and very brief douching of the back of the neck with cold water, to be followed by active dry friction to assist or to promote the restoration of the circulation in the parts. During the douche the hair should be carefully protected from the water, for wet hair would only prolong the injurious effect of chill. Meanwhile, the nose itself may be treated with insufflation of a fine powder composed of two drams of subcarbonate of bismuth with six grains of aristol.

Bearing in mind what we have said about internal inflammation causing hyperesthesia or great sensitiveness of the corresponding area of skin over the seat of the inflammation, any area of chronic inflammation should have the corresponding cutaneous surface carefully protected. In health, if a cold hand suddenly be placed over the precordium, the heart will give a bound, but so all cases of heart trouble, whether the result of pericarditis or endocarditis, are very sensitive to surface impressions, which would not normally be felt. This explains the beneficial results following applications of large belladonna plasters, which should cover the whole area of the skin over the heart, but these facts are equally applicable in all chronic inflammatory conditions, whether of the lungs or of the pleura. Chest protectors on that account are reasonable. I prefer the application of cotton batting to any other such measure. Similarly every patient with chronic diarrhea should have his abdomen covered by some equivalent protection. In chronic, long-standing bronchitis I have the patients wear both shirts and drawers made with perforated chamois skin, worn just over a light undergarment. I have often been told by such patients that they could spend their winters at home, when before they used these protections to the skin they were unable to do so. Osler says in his Practice of Medicine: "Thus, in the convalescence from measles and whooping cough, it is very important that the child should not be exposed to the cold, particularly at night, when the temperature of the room naturally falls. In a nocturnal visit to the nursery—sometimes, too, I am sorry to say, to a children's hospital—how often one sees children almost naked, having kicked aside the bedclothes and having the night clothes up about the arms."

In my practice I have all such children, while tossing about, struggling for breath, and those exposing themselves, put into bags of canton flannel, drawn about the neck so as to prevent them from exposing the skin to the cold air.

70 East Fifty-fourth Street.

GENERAL MEDICAL EDUCATION: THE ONLY RATIONAL PREVENTIVE MEDICINE.

By A. L. SORESI, M.D.,

NEW YORK.

Preventive medicine is almost entirely limited to the suppression of infectious diseases, which are by no means the worst ones affecting human beings. We must consider as disease any condition differing from the physiological harmonious constitution and functions of all the organs essential to the physiologically perfect human being. Therefore we must consider as diseases such conditions as premature old age, imperfect human beings, showing a more or less marked degree of monstrosity caused by lack, distortion, misplacement, or excess of any part, organ, or functions, such as the blind, deaf and dumb, cripples, hermaphrodites, hypospadiacs, etc., psychic derangements, imperfect functions of the eliminatory organs, all organic diseases, tumors, etc.

That little has been accomplished by preventive medicine up to the present time, is proved by the fact, that diseases are raging and claiming their victims almost in the same manner as before our knowledge of their nature was as advanced as it is now—not to accept the ideas of some observers, who think that diseases are on the increase. The questions therefore arise: Whose fault is it, that not more has been accomplished? Is our knowledge insufficient? Are our sanitary regulations incomplete? Is it impossible to eradicate diseases and is then preventive medicine only a dream?

Diseases are attacking human beings in so many open and insidious ways and there are so many coefficients which help their diffusion, that we must not look upon the problem of their eradication as one concerning and of interest only to the medical profession, but a problem which must be of the highest interest to every intelligent human being.

With this thought in mind, I will try to demonstrate that there will never be real preventive medicine, not even against infectious diseases, if the medical profession is left alone in the fight; that the only way of attaining success is to have the intelligent cooperation of every intelligent person; that in order to have such indispensable cooperation, every one should know what diseases are and how to fight them; *that a general compulsory medical education, based on a good practical knowledge of anatomy, physiology, pathology, and hygiene, beginning with the elementary training of children, together with a general diffusion of such knowledge through all grades of society, is necessary to this end.*

I will take up, first, the subject of prophylaxis against infectious diseases, because it is the part of preventive medicine best understood by the medical profession. We know that infectious diseases are caused by microorganisms of different species; we know how these microorganisms grow and attack human beings. In theory, infectious diseases could be eliminated in a very short time, by destroying or making harmless their agents. When Pasteur demonstrated the life of microorganisms and Lister proved how disinfectants killed them, the doctors of that time had visions of exterminating all infectious diseases with more or less powerful disinfectants. We saw the futility of fighting infectious diseases, with disinfectants, because by killing the microorganisms we were also killing the living cell of the organism which was invaded by the infecting agent, so that the results were exactly the same as if one, seeing a person attacked by a ferocious animal, should fire at both; the animal would be killed, but so would the person attacked. The wonderful progress of late years has brought forward inoculation of toxins, antitoxins, sera, etc., and the almost miraculous results obtained against diphtheria by Behring's and Roux's antitoxin and the more dubious against typhoid fever and other diseases, have given to the medical men and the cultured laymen the idea that we are on the right path and very shortly all infectious diseases will be prevented by such means. But in a few years from now the medical men will see that we were as mistaken as the men of the antiseptic period, and sera and vaccines will be used as we now employ antiseptics, that is to say, they will be used only in certain cases and without the illusion of eradicating all infectious and contagious diseases with them. The reason for this is apparent. If we admit the realization of the most rosy dreams—the possibility of finding the specific for each infectious disease, or a specific which would kill or prevent the vitality of all microorganisms—we would, in the second case, also kill or prevent the vitality of microorganisms which are indispensable to some processes of metabolism, such as fermentation. In the first case to obtain real, actual results, we should inoculate each human being with many different active principles, which are not found in the normal healthy human body; and who can foresee the possible damage that such active principles, which are and should always be foreign to the normal human body, would produce, if not immediately, in the future, either on the present or on the coming generations? To fight infectious diseases through vaccination, inoculation of sera, etc., is only a moderate improvement over the old way of fighting them with drugs and antiseptics, if their cause is not removed.

But the medical profession has not limited its activity to the preparation of sera and vaccines; it has other prophylactic measures, so let us briefly examine some of those proposed and adopted by the medical profession in some of the best known infectious and contagious diseases and study the results obtained.

Tuberculosis. We know its agent, how it enters the human body, the lesions it produces, how it multiplies itself, what its conditions of life are. We know practically everything relating to this terrible disease and thousands of persons are engaged in preventing its diffusion and an enormous amount of money is being spent to this end. Sanatoria, preventoria, and special open-air schools have been built and more are contemplated. We have proposed sanitary regulations. Almost all modern cities have made it a misdemeanor to spit in cars and public conveyances. Lectures and exhibitions are given freely to the public; we have done what we think is in our power to stamp out this plague. In theory we could eradicate tuberculosis in a few years, but we must admit that the progress we have made since our knowledge has been accepted by the medical profession, has not been in accordance with what was reasonably to be expected; some even claim that tuberculosis is on the increase. With all our precautionary measures and labor expended, we find that it has spread to every inhabited part of the world, and even old villages in remote parts of the country, which were some twenty years ago immune, are now infected with tuberculosis.

Why does this happen? Because the social value of our sanitary regulations is not understood by the public and therefore the social causes on which tuberculosis grows are not removed. Nobody, even in towns where it is a misdemeanor, takes very much notice of persons who spit in the streets, and, in fact, I would like to know how many people refrain from doing so, where the air dries much more quickly than in any public conveyance and where the winds carry with the dust the tubercle bacilli into every house, every corner, and on everything exposed to the atmosphere.

But that is not the only strange thing one can observe about these sanitary precautions. In every city children are playing in the streets and often in clouds of dust which, entering their mouths and nostrils, is ingested and forced through the bronchi and lungs by the rapid inspiration which takes place while they are running or playing games. The quiet observer can then candidly inquire what is the use of taking so many precautions to build sanitary houses, schools, etc., to teach mothers how their children should sleep, how to keep the house clean, etc., when a child breathes and ingests more impurities in an hour while playing in the street than during all the time he is at school or in his home eating and sleeping. If everyone knew what health really means it would be easy and not at all expensive to prevent the majority of infant tuberculosis, besides many traumatic injuries, by compelling builders to make the roof of every house a playground, safe and sanitary for every child. A city would then have, at very little cost, an enormous playground as large as the city itself that would be as desirable as if it were in the open country and the outlay would be so insignificant that it need not be taken into consideration. But the first to protest would be, in all probability, the mothers who would prefer to have the roof at their entire disposal to dry the laundry than to have their children play and breathe pure and healthy air, as

well as saving their lives by not running the risk of being injured by street cars, trucks, and automobiles.

A child is attacked by diphtheria or scarlet fever, measles, etc. The disease is, so far as the morbid entity is concerned, exactly the same whether he is the son of a millionaire or the poorest laborer, but the contagion, that is, the danger to society, is quite different in the two cases. The son of a millionaire will have a doctor who will take the necessary care not to carry the infection from one house to another, because he can devote time and money to personal care by changing his clothes and not coming in too direct contact with the patient, having a good trained nurse who attends to all details of the disease and simply reports them to the doctor. The trained nurse also knows how to take the very necessary precautions so that the disease is not communicated to other members of the family. A well-ventilated room is provided for the patient; whatever science has devised for the treatment and prevention of the spread of the disease is applied, and the case will remain an isolated one. Nobody else will be infected by him.

Let us examine the condition in the other case—the poor man's son. The doctor is very likely a lodge physician who has to visit an enormous number of patients daily and, being in a hurry, he does not have time even to wash his hands, often because there is no water in the room. The place where the patient lies is, in all probability, a dark room, without air and in which other members of the family have to live and sleep. The poor mother certainly does not know how to take the necessary measures against the spreading of the disease.

The family of the sick child is composed, besides father and mother, of some boys and girls. One of the girls is a saleswoman in some store where ladies' wearing apparel is sold. The girl has been sleeping in the room with the patient and attending the little brother or sister after working hours: her hands and wearing apparel certainly become infected. The next day she goes to the shop and helps ladies try on, for example, a pair of gloves, choose a muff, a hat, a corset, or any of the accessories of a woman's wardrobe. Still better for the propagation of the disease, she will help madame choose some garments for her little son or daughter. She will pet and caress the child in order to keep him quiet and look pretty to induce the mother to buy. Can one imagine a better means of diffusion of infectious diseases? Such examples could be multiplied and are all well known to the physicians, but the point here is not how infectious diseases diffuse themselves so much as the social conditions which make such infection possible and which are not appreciated enough either by the medical profession or by the public. The same disease among the wealthy and educated people is limited to one case, but among the poor it is the origin and cause of numerous other infections entailing the unavoidable loss of life, health, and money.

Typhoid fever is known to be diffused mainly by water, milk, fruits, and vegetables, as well as by direct contact. Thousands of books, articles, and lectures have been written on the subject. Well, many cities supply their citizens with water that is unfit, not only for drinking purposes, but, in many cases, even for bathing or washing.

Cholera is making thousands of victims in Oriental countries and, although we are lucky to escape it on account of the distance from the countries where it is endemic, it gives us another good illustration of what modern prophylaxis is accomplishing. In many Eastern countries and Mediterranean ports the streets are used for toilet purposes; bodies of dead animals are left to putrefy, and the "sanitary squad" is unknown. The medical men have been trained in the best colleges and have proposed the best sanitary laws and yet the spread of cholera is almost as bad as it was before the medical profession knew anything of its nature. Even in southern Italy it has spread, notwithstanding the very best sanitary measures taken by one of the foremost medical bodies of the world—the Sanitary Council of Italy. One sees there that soldiers and policemen have had to be called out to help the medical men carry out their sanitary precautions; continuous and violent demonstrations against the authorities have taken place very often and, instead of applying the sanitation advised and imposed by the government, the people burn candles to some saint for protection.

But one does not have to go to the far Orient to see that sanitary laws are not enforced as they should be. The Board of Health requires that some infectious and contagious diseases be reported; that a sign be placed on the door of the place where the affected person lives. How many persons object to having such a sign on their door and ask the doctor not to report their case to the Board of Health? How often does some member of the family where the affected person lives even threaten the doctor if he reports the case?

I have already referred to the laws forbidding expectoration in the streets and public conveyances. Now these sanitary laws are perfect and rational and of not difficult application, but they are enforced about as much as the elementary Oriental laws mentioned above, that is, they are not enforced at all, or so very slightly that the benefit derived from their enactment is small. Very few would take the trouble of having a person arrested for expectorating on the street and even the magistrate is very lenient and applies the minimum penalty. In the popular mind the offense is not a very grave one; the importance of the laws is ignored and they cannot appreciate it.

Consider for a moment the way the glasses are washed in many of the so-called ice cream parlors. The water is generally dirty and of such a color, that there can be no doubt about its being unfit for cleaning. Nevertheless, thousands of people drink and delight themselves with the beverages and refreshments served in those unclean dishes. Stand on a corner and look at a man selling hot frankfurters and you will see that cleanliness is not regarded as a factor to help the sale.

Is, then, prophylaxis useless and are we wrong in advocating it? The idea of prophylaxis is as good as any human idea can be and the wonderful success obtained in fighting some diseases is the best proof that we are on the right path. We have been very successful in preventing certain diseases, which some years ago were thought to be incurable and unpreventable and malaria is the best illustration of what a really scientific prophylaxis can accomplish. I will consider, for brevity, only what has been accomplished in the prophylaxis against malaria and what has not been accomplished against tuberculosis, because I think the success in the case of malaria and the unsuccess in the case of tuberculosis will give us the indication of what we should do in the other infectious diseases.

On account of malaria, people used to die by the thousands or lead the most unhappy life after having been infected. Thousands of square miles of land were uninhabitable. Quinine was discovered to be the specific for malaria, but people and lands were in the same condition. Grassi discovered that the essential element for the prosperity of malaria was a kind of mosquito. Following this discovery he started the most brilliant campaign in the history of medicine to prove that the only possible means for the diffusion of malaria was through the anopheles; that it was possible to live in the most infested place without contracting malaria, provided one was not bitten by the anopheles. Grassi and others proved that by eliminating the anopheles malaria would disappear, but still malaria was as prevalent as before its manner of infection was so mathematically proven.

The thousands of victims, who by, either losing their lives, or becoming cachectic, were lost to society, the immense acreage of land that was lost for profitable cultivation, aroused the interest of the legislators and financiers who saw it was a good investment to save these lives and make cultivable the large tracts of land. So they asked the best engineers to study the problem and the result was that they did not try to kill the mosquitos, but they tried and succeeded in making the life and proliferation of the mosquitos impossible. They saw that the mosquitos were living and proliferating because of stagnant water. They asked millions to drain the ground and where formerly there was nothing but marshes, death, and misery, now, after a few years, those places are inhabited by thousands of healthy and prosperous people.

Tuberculosis is the most quiet and insidious disease. It attacks its victims by the millions, one by one. It does not make its victims suddenly, only in certain localities and at certain places. It is always among us, winter and summer, and it makes its victims quietly, without éclat or alarm. We are accustomed to it and we grow very careless. We physicians understand perfectly well the great damage it is causing in our ranks, but we can do nothing. Social conditions favor tuberculosis and are against our campaign. Legislators and financiers, who have seen the good investment in prophylaxis against malaria, fail to appreciate as they should, that some social conditions are the real cause of diffusion of tuberculosis and we have resorted sometimes to prophylactic methods which are not only ineffectual but really terribly injurious. Our systematic examination of people before being admitted to factories or public offices, or after they were employed, has shown how common tuberculosis is, but too often the unhappy person affected by the disease, after having been discovered to be consumptive, did not obtain the desired position or has been discharged. The effect of our prophylactic examination has then been, in many cases, the loss of the means of earning a decent living, with the inevitable resulting malnutrition, which we know favors the culture and diffusion of tuberculosis. It is plain, therefore, that if we could create a medium, such that people could understand the value to society of a healthy population, it would be possible to drain out of the social ground, the conditions which make possible the existence and diffusion of infectious diseases, because they would understand how good an investment of money and energy it would be.

The problem of infectious diseases is not only a microbic one. I would dare to say that it is more a social than a medical problem. Medical science will never be able to prevent the existence of infectious diseases, until social science has been able to eliminate the conditions which create the favorable ground, where infectious diseases grow and multiply.

How many, even among the medical profession, realize that overcrowding in small flats and in poorly ventilated factories is one of the great causes of diffusion of a number of diseases, and not only the infectious ones, but the nervous and psychic, and that such conditions are a menace to the community? How many have the conviction that poverty is one of the most dreadful diseases and that any law bettering the financial condition of the poor is a better and more valuable step toward public sanitation, health, and human happiness than the best and most efficacious serum? Do we try to convince the wealthy class and, first, are we convinced ourselves that the condition of half-starvation, overwork, unsanitary conditions, and lack of rest of a large number of human beings is the cause of the greatest number of diseases and that it is the duty of the dominating class, if only in their own interest, to put a stop to such a condition, because their own health is endangered? Disease is no respector of persons—the poor, the rich, the intellectual—all are attacked alike and one as savagely as the other. Tuberculosis, diphtheria, pneumonia, and many other diseases would not make so many victims, and finally would disappear, if the sanitary condition of the poor was what it should be, and by sanitary condition are meant all the conditions leading up to a healthy life—good food, rest, good homes, and proper clothing. Are the medical profession and the intellectual class convinced as they should be, that all the laws made to protect the workman are in the end of benefit also to themselves? Laws regulating child labor and the sanitary condition of factories are of benefit not only to the working class but equally to the higher classes. Children and working people in poor health are more liable to be victims of diseases and to become the means of diffusion of them.

What makes then such a social condition possible? Nothing but social ignorance. How many of those constituting the human family have definite ideas about diseases? It is safe to say about one or two to a thousand; that is, those connected with the medical profession. The vast majority do not know anything, or have so little and incomplete knowledge that complete ignorance would better express it. The poor medical man, therefore, is left not only alone in devising and applying means to fight diseases, but too often his work is badly hampered by the ignorance of others. The sanitary laws which he proposes, if approved by the legislators, remain in the great majority a dead letter, because people, not understanding them, do not appreciate their importance, making such laws effectual by insisting on their enforcement. No law that has not the appreciation and the strong approval of the majority of the people is really a law; it is nothing but a practical joke, or the expression of the wishes of a few. And it is almost useless to work for the advancement of medical science, when our knowledge is not taken advantage of, when people do not understand that disease cannot be considered as a private affair. It concerns the public welfare when a person suffers from a physical or moral disease. He must be

regarded as a disabled member of the large human family, not only becoming a charge when he is no longer able to perform the work which he is expected to do, but a menace either because the disease can be communicated to others, or because he can procreate human beings who will in their turn become a charge and a menace.

It must be understood by the public that every animal can be a danger to the community and that any wrong idea about diseases is favorable to their diffusion. I say intentionally every animal, because, for instance, a dog or a cat, in a flat where there are children, can diffuse more diseases than a child suffering from diphtheria, whereas very little or nothing is thought of it.

The importance of the ignorance of the vast majority of the population, as the greatest factor for the diffusion of diseases, can be appreciated when the fact that diseases are the worst enemies of the human race is taken into consideration. To fight successfully an enemy one must know who his adversary is, his habits, his strength, his weak points; in a word, one must have all the possible information about him. As every individual can be attacked at any moment by diseases, it is only logical that every one should know as much as possible about them.

Some claim that diseases could be completely eradicated if people had more confidence in the medical profession. The so-called distrust of the public toward the medical profession is perfectly understandable and excusable. We have for centuries kept medical subjects out of public discussion. We have now broadened our views by coming into more direct contact with the people, but we must go further, if we want to obtain good results. We have shown our progress, but we have hidden our shortcomings, we have promised things that we could not give, and, although we have acted in good faith, we have failed and must stand for our failures. We have not to forget, that the public will brag more about one of our failures than talk about thousands of our successes and we must show to the public our good faith and willingness to do our best for their benefit. We must teach them that medicine is not a mathematical science; that we really do the best that can be done and that nobody can do any better. We must give people confidence in ourselves by educating them to appreciate our work and cooperate with us. We must convince them that there is no such thing as a medical trust; that what we ask, is that nobody should take care of the infirm, who has not a certain degree of general culture demonstrating that he has the right mental attitude to study medicine; that nobody should practise medicine, who is not trained in a certain course of studies, but that there is no necessity of more freedom because the medical profession is free and open to all. We have to educate the people to understand that, if we ask restriction in the practice of medicine, it is only to the advantage of the people themselves. The more quacks there are the more business for the good physician. That our restriction requires only the necessary knowledge to be able to practise medicine; that we do not impose on each M.D. the doing of certain things. We want the M.D. to learn the elements and then he has to use his brain and he has the broadest liberty to do as he sees the case requires. That we know our shortcomings and we are trying to have a higher standard of education for the persons, who intend to devote themselves to the practice of medicine; that we want to make it more difficult to become an M.D. because we try to have the best fitted as far as intelligence and morality are concerned. And if we can convince ourselves that the cooperation of the people is indispensable and then convince the people that a good knowledge of the human body is absolutely necessary to keep one's health, and that health is the most necessary factor of human happiness, we will have done more for the advancement of preventive medicine that if we study only for the advance of medical science. What we need immediately is not additional, new medical knowledge; we need people who can understand and appreciate what we already know and put into practice our present knowledge.

But if social ignorance has made impossible the prophylaxis against infectious diseases and created a medium where the medical men cannot accomplish their duty as they should, it has done even more harm in regard to the other diseases of non-infectious origin. Nothing or little is done as prophylaxis against diseases, which are perhaps more easily preventable than the infectious ones.

Constipation, which is very little thought of, is claiming more victims and doing more harm than the white plague. Any physician has only to examine his records and he will be surprised to find that the majority of his patients are suffering from constipation, which had predisposed them to a number of other ailments, for which they consult a physician. A mother will never think of consulting a physician because her children are constipated. In fact, it is seldom that she notices that they have that difficulty and, if she does, no attention is given to it. She has been constipated and never did anything, except take occasionally some purgatives. She does not understand that constipation is really a disease which predisposes the body to a great number of other diseases. The slow and continuous absorption of poisonous products of decomposition of the intestinal contents, is more dangerous than the absorption of alcohol or any other drug, because it works on the system continuously and unnoticed. For a long time I have followed the most celebrated crimes, the so-called passionate crimes caused by women, and I have always found that the woman in the case, with very few exceptions, was suffering from constipation. This trouble, which is the root of so many evils, should be completely eradicated, except where there is organic disease, if mothers and teachers had a better knowledge of the functions of the alimentary canal. How many diseases can we trace from the habit of drugging with patent medicines, antifats—medicines which will cure all ills, as kidney, liver, lung, and stomach troubles, without the person's knowing whether the trouble exists or not? Does the public help us in our campaign for pure and sanitary foods?

What is done to prevent the coming into this world of human beings, who are unable to stand the strain of life, because imperfect, as the blind, deaf and dumb, or sickly at birth? We all know that not more than one-third of all human beings are not as healthy as they should be, therefore unable to give society a full share of work and enjoy life as every human being has the right to. We hear people talking about the decadence of the race and of race suicide. Among the many foolish things that have been said by prominent men is that the reduction of the birth rate means the suicide of the race.

Nobody seems to think that race suicide is not the limitation of birth rate but the bad crop of new human beings caused by the unscientific way in which human beings come into this world. Venereal diseases are ignored by our legislators who talk about race suicide. Giving birth to beings unfit and imperfect is thought to be only an unavoidable accident, and the intelligent legislator asks for a limitation of marriage, by giving the prospective bride and groom a clean bill of health, as if to procreate children it were necessary to have the approval of a parson or of a judge.

Race suicide is putting into this world human beings unfit. Race suicide is a problem of quality and not of quantity, and the quality will never be improved until the ones who can procreate human beings, that is, all men and women, know the best way of doing so. In this respect, we are as scientific as were our forefathers of the stone age, who at that time did not have, very likely, the many diseases that are now torturing the human race.

Real race suicide is infant mortality, a condition which could and should be prevented. What is the use and advantage to the present and future generations of a woman putting into this world six children, for instance, when only one or two of them reaches the age of being useful to himself and to others? It is a terrible tax put on the human family to have children die. The mother, while pregnant, is unable to accomplish much work; money, time, and energies must be spent to keep a life which is going to be extinguished before it is of any use. We would hear less foolish talking about race suicide, if we teach every man and woman that the genital organs must be in the best of condition to produce a healthy human being; that the production of a human being that cannot enjoy life is the worst crime, because it is committed against one's own creatures.

Another element, absolutely neglected by the ones talking with so much authority about race suicide, is the fact that in relation to sexual questions we have not made the slightest progress. We still think chastity a virtue and we honor the ones who have made vows of chastity and, further, we allow them to talk about race suicide. Chastity is not only not a virtue, but in relation to race suicide it is the blackest crime against society. If we were all chaste there would be not attempted race suicide; there would be absolute race destruction. And when we hear men and women, devoted to chastity, preach against scientific limitation of birth, we have to wonder, why people talking that way are not sent to the insane asylum, instead of letting them preach the principle of morality and pretend to be an example to other human beings.

The study of medicine in a logical way, if necessary for every human being, should be absolutely essential for anyone who is taking care of children and who is to advise, even if only in a moral way, his fellow beings. How can a teacher, for instance, take care of a youngster, either boy or girl, at that critical age of puberty, adolescence, when the genital organs are developing and waste more energy than the majority of observers seem to believe? He feels that something is working in his system, like a worm would under ground. He does not know what is the matter with him and the teacher, minister, or parents will tell him to study more or to say more prayers. No one seems to understand what is going on. The parents are ignorant themselves, and, even if they notice something, they believe it is better not to say anything. The girl or boy will know all about it soon enough. And how will the adolescent know? Usually through some one, who is perverted and corrupted and through sleepless nights without rest, at the very time when rest is most essential.

But how can teachers and a part, at least, of the clergy be expected to understand this phenomenon when even in our modern civilization here in New York, we ask that a young woman teacher should not get married because if she does and has children she will lose her position? So that the majority of the ones devoted to the instruction of children are men and women vowed to chastity or "old maids"—thus violating the first and strongest law of nature—the necessity of reproduction. Teachers should be fathers and mothers and no one who did not develop all his physiological powers in the very best physiological way, should be a teacher. People who are compelled to repress the most physiological feeling—the feeling of reproduction—should not be teachers. They will never understand the age of puberty. To thoroughly understand an adolescent, it requires not only tact—tact alone would not make one a good diagnostician, a good surgeon, a good lawyer, a good minister, or a good singer. It requires unbiased knowledge of the anatomy, the physiology, and the pathology of the human body, and certainly a great number of youngsters have been ruined, sexually and morally, by the ignorance of their teachers and parents. I remember the case of a young boy, who was expelled from school to be sent to a reformatory as being incorrigible and upon physical examination, I found that his genital organs were abnormally developed and kept very unclean. By performing a circumcision and giving him good advice, the boy went back to school and was as good, or as bad, as the average boy.

Often teachers and parents scold an adolescent and punish him, never thinking that he might be ill. It is as necessary to have a knowledge of anatomy, physiology, and pathology to understand and appreciate the phenomena of life as it is to know a language in order to understand a book written in that idiom.

So much is said about the future of the race and the necessity of a good, sound education which will leave a mark on one's personality during all his life, but who knows the physiology and physiopathology of children? Teachers and parents have not enough knowledge of the human body and mind, to be able to detect some facts which would so help the cause of first education, as to put it on a real scientific basis. If the teachers are already doing so much good, what would they not be able to accomplish, if they had the necessary, unbiased knowledge from understanding the physiology and pathology of children's actions?

There should be no laymen about medical questions, as there should be no analphabet, that is, every one should be able to understand the problems of health and understand and appreciate what the professional medical men do, just as every one should be able to write and read. Some will say that hygiene is taught in our schools, but hygiene is not a science *per se*. It is the result of knowledge gathered from a number of sciences, such as anatomy, physiology, pathology, therapeutics, and to teach hygiene *per se* is the same as teaching law, architecture, engineering, archeology, or any other of the modern branches of science to a per-

son who has no elementary culture. It would be absolutely impossible for him to understand. Hygiene is not appreciated; it is an empty science and a bore.

Of all the things we studied in school, when we engage in any profession in practical life, we have forgotten at least 90 per cent., because they are of very little use to us. But we live every day with our mind and body; we need them every minute. Without health we can accomplish nothing, so that it is easily seen that a knowledge of the elements necessary to maintain health is the most necessary.

In our schools many branches of science are taught more or less thoroughly, some as indispensable and necessary elements to acquire other knowledge, some as practical knowledge useful in civilized life, some to give the student a special culture, and some for mental discipline. I do not think that there is a knowledge more indispensable, besides writing and reading, than the knowledge of the human body. Its anatomy and functions are the most complex, highest, and interesting of all the manifestations of nature, because all the manifestations of nature refer to us, as we are built and as we act. I cannot imagine a person who is called cultured, that does not know himself. As for developing the powers of the mind, I would like to know if there is any science that compares with it.

The result of a general medical education would lift the standard of morality by making plain, that human happiness is based on a sound and physiological balance between the powers of the mind and of the body. That it is foolish to make laws which are not in accordance with the fundamental laws of physiology; that nobody can be happy and make others happy unless he is healthy and physiologically developed; that diseases can not be cured, but can be prevented; that every human being has the right to be healthy and strong and, therefore, parents who, through ignorance, do not take the proper care of their offspring or reproduce imperfect human beings, are guilty not only against society but also against their own creature; that the welfare of every human being as an individual, is strictly connected with the welfare of the community.

There are sentimental feelings opposed to the teaching of anatomy, physiology, and hygiene in a practical way. It is said that it would tend to make men and women skeptical and that they would lose the poetical side of life. This is the grossest and most stupid argument that could be offered. From a religious point of view—and I have to mention it because, unfortunately, religion has taught a very false sense of modesty—to know what the Lord has done, is to admire the greatness of the complicated human machine, and I cannot see any reason why, as long as the Lord has made us as we are, students of religion should not take the matter in their hands and teach, along with the moral, the physical basis of life.

We have to understand well ourselves and teach others that there is only one morality and that is physiological morality; that what we call morality is an empty word if we do not mean the acts which are the result of a body physiologically perfect; that all laws should relate to the physiological functions of the body as the body is built; that no one is better than his physiology, and that only sound morality is what should be termed physiological morality. The perfect man, therefore, is one who thinks and acts according to his physiology, for any human being when the physiological support and *rapport* of his organs are broken, becomes a pathological subject and will act accordingly. A dissemination of the knowledge of anatomy, physiology, pathology, and hygiene would make a better class of people, because they would care more and take better care of their health, and they would understand that there can be no sound mind, where the body is not physiologically perfect. The ignorant moralist who said that the body is the slave of the mind and based his morality on that principle, has done more harm to the human race than all the diseases combined. There is no healthy mind in a body which is not physiologically in good order and we know well enough now, how the sweetest girl can be changed into the most irritable person imaginable by ovarian trouble. We know that a little growth on the skull can make a human being an epileptic and therefore irresponsible. We know that the so-called case of gall-bladder, is always an unhappy being, who makes everybody living with him unhappy. We know how harmful for the mind and for the body is constipation with its slow absorption of poisonous ptomaines.

And I think that it is an insult to Divinity even to think that the knowledge of the human body and its functions would make men and women less respectable in the eyes of each other. Ignorance is not respectability. Ignorance only leads to prejudices, which make human beings more like animals of lower species. Only a fool must be afraid of knowing himself and how he acts. Ignorance has created a most false sense of modesty relating to some important acts of metabolism, as urination and defecation, and has made a kind of sanctum of the genital organs, especially the female, with the result of enormous suffering from diseases of digestive, urinary, and reproductive organs, which, in their turn, lead to a number of mental diseases, wreck many lives, and make many homes unhappy.

So far as the poetical side of life being lost and the hardening of one's feelings, by studying well the human body, we have only to answer that the greatest surgeons, who are thought to be heartless all the world over, are generally the gentlest human beings with their fathers, mothers, daughters, sisters, and friends, and one has only to observe the conduct of persons connected with the medical profession—nurses and doctors—with children and old people, who often tax to the utmost the patience of the most patient relative and who are absolutely nothing to them, to see that if there is any result from the study of medicine, it is to refine the sense of kindness which is inborn with every normal being.

But the strongest objection comes from the medical profession. Some say that unfortunately we already have a great number of quacks and people taking care of themselves, without consulting a regular physician, and therefore, if every one had a knowledge of medical science, quacks would be innumerable, and the spread of disease would be dreadful. This objection is absolutely worthless, because the ones who go to the quacks, or who treat themselves, without the advice of a competent physician, are the more ignorant, and therefore are the ones who need more to be instructed and then, having a general medical education, would understand, that the very best man to give medical advice is the man, who makes his only business the medical profession, after having had a special training.

Now we have a certain limitation to the practice of medicine, but we see that a great number of per-

sons who are not in any way, or in a slight way, connected with the medical profession—as the medical profession should be understood—give advice and administer remedies with the certain danger of having anything administered or advised by incompetent persons. When everyone had benefited by a general medical education, he would be better able to appreciate the services of his physicians, would be able to help him in making his diagnosis and in administering the proper treatment, and would appreciate much more the good work his physician was doing. The medical profession would then be in exactly the same position as far as public appreciation is concerned as are now the professional singers, professional writers, professional ball-players. Every one of us is able to sing, to write, to play certain games, but we leave to the professional ones and pay them for giving us the very best that can be had, for the very reason that we are able to appreciate who is the good writer, the good singer, and the good player, because we know the elements of these manifestations of human activity, and nowadays writers, singers, and professional players are certainly making more money and enjoying more reputation than they were in the past centuries, when only a few had the privilege of a general education, which was not high enough to make people appreciate the work of professional singers, writers, or artists. And that that is the plain truth is easily seen when we examine the condition of some of the other professional people of former times. Dentists were considered only as charlatans, while nowadays we have as much consideration for them, as we have for any other professional people. Actors, singers, and players were all considered more or less as belonging to the class of beggars, while now they are enjoying the greatest consideration and every country is proud of them. Not only the moral but the financial condition of all these professional people has been bettered. Homer, Virgil, Dante, Shakespeare, Goethe, Cervantes, Le Fontaine, Michelangelo, Voltaire, etc., have certainly not been able to make one hundredth part of what a second rate professional writer or inventor is making nowadays, since knowledge is more generalized.

Scientific reasons tell us that we must diffuse medical knowledge. Medicine, although as old as human beings, as a real science is only in its infancy, and we must well understand that the more rapidly it will progress the more people know its elements and are interested in it. Often it is not the professional man interested in a special branch who, by his genius, will open up a new path to the progress of science. Frequently it is an outsider and we have the best proof in our own science. No individual has ever been such a striking factor in the progress of any branch of science, as Pasteur has been to the medical one. Pasteur was not a physician; he was an outsider.

Medicine should be divided in this way—the science of medicine open to all, while the practice of medicine should be limited to the ones who, after a regular course of studies, intend to take it up as a profession, having the moral and physical qualities for it.

This limitation should not be understood as an indication that physicians think to be the only ones, who have the intelligence to understand medical subjects and have honest intentions, but only because, as in every other profession, the man who makes his specialty any kind of work, is in that special line better than people of even more intelligence, but lacking the necessary daily training. No one would say, for instance, that the engineer of any of the trains running at high speed by the hundreds every day, has more intelligence or is more honest than the President of the United States or the Chief Justice of the Supreme Court, or of any of the presidents of the big colleges; and, at the same time, no one with enough brains to be considered a man, would prefer to have a fast express run by any of the most honest and intelligent people of the country, as the above mentioned, than to have it under the control of an experienced engineer, for the only and obvious reason that it is the engineer's business. The same considerations should prevail with regard to medical subjects. Every one should be welcomed and be able to show his ideas, the same, as anybody can present before the public and patent anything he thinks worth while, but it is the province of the professional men who make a specialty of it, to apply those patents when found valuable.

It would be exactly the same, to continue the example of the engineer, as if anyone should think that he had invented a faster and better engine than the ones now in use. Nobody would consider it a limitation of one's liberty if the directors of a railroad should ask that their best engineer should try it, and, when found valuable, adopt it, instead of letting the inventor run himself, for the first time, his engine attached to one of the trains carrying passengers. The question of having the public take an interested part in medical subjects has two sides, which must be considered very seriously and impartially. It is true in medical science, as in any other part of human knowledge, that laymen can sometimes see certain sides of a question in a better way, than the man who has spent all his life studying it; but, at the same time, it very often happens that laymen think that they have made the greatest discovery, which, in their minds, should revolutionize the world, whereas, when presented to a man who is competent to judge the merits of the invention, it is found out, that it is based on a false and impracticable principle and, therefore, the discovery is absolutely of no value. So that only the intelligent cooperation and mutual assistance of the layman and the expert are necessary to make any progress in medicine, as in any other branch of science.

And the fact that the medical man alone can accomplish absolutely nothing, I hnk, I can prove with a few examples. Every time we have been successful in preventing any disease, we had the cooperation of a number of men, who had no connection with medical science. Malaria has completely disappeared where, and only where, the engineer has been able to drain the soil. Scurvy has disappeared as the result of better steamship accommodations. Typhoid fever has almost entirely disappeared, where engineers have given a good and abundant water supply, and is still making victims by the thousands in cities where the financiers and engineers have been unable to do so. It is said that the country is more healthful than the city, and in part it is true, but the city can be made as healthful as, if not more healthful than, the country, with the cooperation of legislators, architects, engineers, etc. Why is the city not as healthful as the country? The only reasons are the dust, laden with millions of microorganisms, and the numerous factories. In the country houses are,

on the average, not as sanitary as in the city. The water, milk, bread, meat, and vegetable supplies cannot be inspected as in the city. Then the dull life of the country has a depressing influence on the development of one's brains and energies. In the city there is too much of an accumulation of undesirable things, which are, in the country, I should say, diluted. We have succeeded in keeping the streets of the city free from human excrements, but we have accomplished little more than nothing, when we have thousands of animals—horses, dogs, cats—that leave wherever they go their excrement, to infest the air and be carried by the wind into our nostrils, mouths, and on our hands and clothes, eating and drinking stuffs. What will then be necessary to make the city more sanitary than the country? Dustless and noiseless streets, elimination of all unsanitary buildings and factories, and the substitution of automobiles for horses, no more people spitting everywhere, and elimination of cats and dogs, which are absolutely of no use and out of place in the city. This sanitary condition will be attained in the near future, but the ones who will deserve more credit than the physicians, will be those who have been able to build economically sanitary houses, to develop the automobile to such a point, that it will be more convenient and economical than the horse, and to the ones who will have invented a noiseless and dustless way of paving the streets. With the existense of the present conditions medical men are unable to do anything, because they are constantly running up against economical and social conditions which render their knowledge of what should be done absolutely useless. The only thing left for the medical man to do, is to educate the people up to the immense value of health, so that the ingenious ones may devote their intelligence and brains to the solution of the sanitary problems, as we understand them and everyone should understand them.

And do we know so much about medical subjects that we do not need more knowledge, wherever that may come from? It is only necessary to open any medical book and see how often the words "Very little is known about the nature of the disease," or, "Its etiology is not yet established," to see that we know very little. To the ones who are overproud of what they know, it would be proper to refer to a little story about a very proud man in the eighteenth century, who was thought to know almost everything, and thought so himself. One day, while he was speaking to a very intelligent lady, he asked her what she would give to know all he knew. The lady smiled at him, and, after a moment, answered: "Well, Mr. Casanova, I would certainly give very much to know all you know, but I would give ten times more to know what you do not know."

So very few facts relating to medical science are established in such a way, that there is no doubt, that we need all the knowledge we can gather from all sources. Many obstacles are in the way of medical progress, caused by social ignorance and the medium resulting from it. We need experimental work on animals and autopsies, not only in order to progress, but in order not to regress. A horrible name full of awful meanings has been invented to designate animal experimentation, and in some of the most civilized countries the so-called vivisection is not allowed, as in England, and we have to fight hard to be allowed to experiment on animals right here in New York. As for autopsies for the study of anatomy, normal and pathological, operative surgery, etc., we have to rely on the poor patients dying unclaimed in the public hospitals, and, owing to the bettering of the financial condition of the public, bodies are claimed so often, that the material is very scarce. Social ignorance, and the medium resulting from it, will make my statement sound strange, when I say that we physicians, who claim that we need bodies for the progress of our science and that the dissecting of the cadaver does not mean lack of respect for the dead person, should give the good example and show that we mean what we say, by pledging ourselves to leave our bodies to the dissecting room, as a condition of entering a medical college; so that people, encouraged and stimulated, should not only not oppose autopsies of their relatives, but should ask for them.

As a conclusion, we must put the medical problem in this way: We want to make every human being as happy as it is possible to be, by being perfectly developed physiologically. We want to prolong, as far as possible, the period of full physiological enjoyment of life. We want to keep the body in perfect working order as long as possible. We want to give everyone the physiological basis of a healthy body and mind, so that he can develop all his mental and bodily powers in the most perfect way.

The medical problem of the future, as presented above, is so broad and, I think, full of seduction for every intelligent and ambitious man, that there is work for every one, who feels inclined to do something in this direction; it is plain that a general medical education is indispensable to this end.

Of course, I do not mean that we should stop working for the progress of medical science, but we have to keep in mind that the greatest and final progress will be the abolishing of medical science itself. I mean, and I want to emphasize it, that, if the people had sufficient medical education to appreciate what we know about diseases, preventive medicine would be a fact of the present time, and not only a hope for a distant future. What we know about diseases is sufficient to give us the possibility of eradicating most of them, even if the knowledge is not thorough in every detail. The obstacles to such eradication are the ignorance of the people about medical subjects, which make them underestimate the individual and social value of health, and the resulting medium which does not allow the medical men to put in practice their knowledge.

75 West Fifty-fifth Street.

DEGENERATION OF THE POSTERIOR COLUMNS OF THE SPINAL CORD IN A NON-TABETIC INDIVIDUAL.

By ALFRED GORDON, M.D.,

PHILADELPHIA,

ASSOCIATE MEMBER OF THE SOCIÉTÉ MÉDICO-PSYCHOLOGIQUE, PARIS, FRANCE.—NEUROLOGIST TO MOUNT SINAI, NORTHWESTERN GENERAL, AND DOUGLASS MEMORIAL HOSPITALS.

Non-tabetic degeneration of the posterior columns of the spinal cord may occur in various organic affections of the cerebrospinal axis in association with other lesions, but as a primary and isolated condition it is extremely rare. The case reported here presents such an occurrence. It is exceedingly interesting from a clinical standpoint, as, apart from the loss of the patellar tendon reflex,

it did not exhibit a single symptom of the classical tabes dorsalis during the entire course of the disease. It was associated with a deformity of the spinal column and a thickening of the lower dorsal vertebræ, at which level the characteristic pathological changes of tabes were present. Clinically, it was not therefore a case of tabes. The case is as follows:

Mrs. E. G., aged thirty-two, formerly telephone operator, was always in poor health. From infancy up to the age of eighteen she was laid up eleven times with various infectious diseases. Married at twenty-three, had three children, all born at term after an easy labor and all now living. No miscarriages. In spite of her general weak condition she was, nevertheless, able to enjoy life and did most of her own housework. When she was sixteen everyone remarked that she carried herself unusually straight, and she herself noticed that there was a tendency for the trunk to draw backward. This tendency gradually kept on increasing, and at twenty-eight was very much pronounced. At that time, *i. e.* four years before she died, she commenced to suffer from paroxysmal pain in the epigastrium. She was taken to the Woman's Hospital, where lavage of the stomach, practised during three weeks, gave her complete relief. At that time she noticed a gradually oncoming weakness of the lower limbs. The latter progressed to such an extent that since then she never was able to leave her bed. At the end of nine months the pain returned, but it occurred only occasionally, and was always accompanied by vomiting. Attacks of vomiting and pain occurred at first only every two or three months, but later every three or four weeks. The diagnosis of tumor of the stomach was then made.

When she came under my observation her condition was as follows: The lower extremities were cold and cyanosed. Raising of the legs was done with great difficulty and not above an angle of 45°, less on the left than on the right side. Patient was unable to overcome the slightest resistance to the movements of the leg. The patellar tendon as well as Achilles tendon reflexes were all abolished on both sides. Babinski's toe phenomenon was present at the first examination, but further test gave no response at all, neither extension nor flexion of the toes. The sense of touch was normal, but the sense of pain was diminished more on the left than on the right side. The temperature sense was normal in both thighs, but diminished in the legs, more on the left than on the right side. It was reversed in the feet—namely, cold was taken for heat and *vice versa*. Patient was almost unable to sit up in bed, but when kept in a sitting position an extremely marked lordosis was noticeable in the lower part of the dorsal spine. There was also a scoliosis of the lower cervical and upper dorsal region, the concavity being directed to the right side. When the patient was placed on her back the lower part of the spine did not come in contact with the bed, and a hand could easily be placed between them.

The examination of the abdomen revealed an interesting symptom. In its upper portion over the median line a distinct hard mass of the size of a small orange was discernible on palpation. It was tender to the touch. The pulsation of the aorta in front of the mass was marked, and, as the sounds on auscultation were quite loud and somewhat prolonged, an aneurysm of the abdominal aorta was thought of. However, other characteristic symptoms of the latter affection were absent, and this diagnosis could therefore not be relied upon. An *x*-ray examination, made by Dr. M. Fisher, showed no discernible osseous lesion, but a faint cloud about as large as an orange was seen at the level of the last three dorsal vertebræ.

Further examination showed no involvement of the sphincters of the bladder or rectum. The pupils were equal and normal in size and shape, their pupillary and other reflexes were normal. Opthalmoscopical examination by Dr. Swindells showed normal eye-grounds. Vision was normal in both eyes. There was no palsy of the ocular muscles. The upper extremity and thorax presented no significant symptom worth mentioning. All the viscera were found to be normal, with the exception of the kidneys. Traces of albumin with a few hyalin casts were present. The blood presented a slight degree of anemia: Hemoglobin 85 per cent. and erythrocytes 4,000,000. A Wassermann test was made several times and it was invariably negative.

To sum up, the patient presented a gradually developing deformity of the spine, with a very prominent forward protrusion of its lower dorsal portion. This was accompanied by attacks of vomiting and pain in the abdomen. Finally the vomiting ceased. Weakness in the lower extremities then made its appearance, which rapidly developed into a complete disability. The tendon and cutaneous reflexes disappeared. At no time was there any involvement of the eyes or of the sphincters. Objective sensory disturbances were present in a mild degree with regard to pain and temperature. Subjective pain occurred in a paroxysmal manner at the level of the protrusion in the abdomen. In view of the skiagraphic picture, and in view of the palpable mass in the abdomen, an exploratory operation was indicated. Dr. J. T. Schell accordingly explored the abdomen, but no evident mass or aneurysm was found. He then thought of a retroperitoneal involvement, which he did not consider wise to remove. The patient made an uneventful recovery from the operation.

The condition remained unaltered. The patient gradually grew weaker and weaker. She finally developed pneumonia and expired.

The autopsy was performed eight hours later. The heart was pale and dilated. The lungs were deeply congested and showed marked evidences of chronic bronchitis; the right lung was bound down by adhesions. The liver and spleen were enlarged. The kidneys were enlarged, and on section the surface was pale. The uterus contained a small fibroid. The right ovary was cystic. The spinal column was markedly protruding in the lower dorsal region and the bodies of the vertebræ at this level appeared very large and thick. The contrast between these vertebræ and those above and below was very striking. Permission was obtained to open the spinal canal and remove only a portion of the cord. A complete examination of the thickened vertebræ for the purpose of determining its nature could therefore not be made. The brain and medulla could equally not be examined.

The removed portion of the cord was placed at first for three days in 10 per cent. formalin and small portions of it were studied for cells. The remainder was placed in Müller's fluid for a period of three months. A histological study revealed first of all no changes in the cells of the cornua. The white matter presented a degeneration of the posterior columns, such as we find in tabes dorsalis

(see Figs. 1 and 2). At the level of the lower lumbar segment, in addition to the sclerosis of Goll's columns, there was also a thickening of the meninges, also of the walls of the blood-vessels. This segment of the cord evidently presents the maximum of the pathological changes, as in the segment

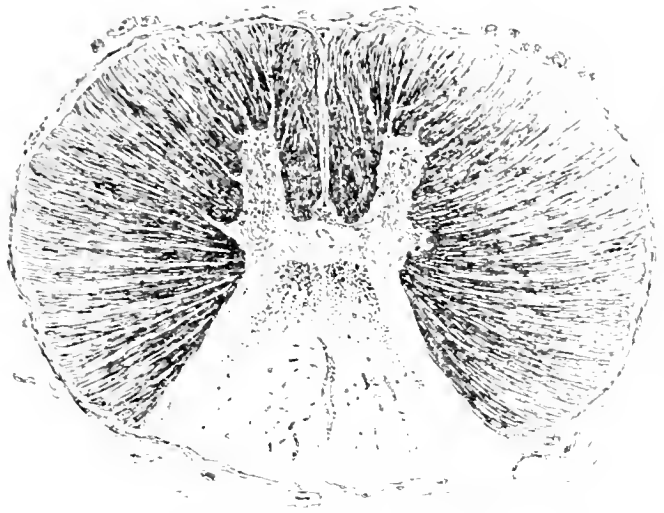

FIG. 1.—Middorsal segment of the cord; degeneration of the posterior columns; stained after the Marchi method; the black dots anteriorly indicate recent degeneration.

above the meninges do not show any alteration. The changes in the cord were confined to the lumbar enlargement. Above it no degenerative condition could be seen. This corresponds to the clinical picture of the case: the patient's disability was limited to the lower extremities.

The pathological condition of the cord is that of posterior sclerosis such as we find in typical tabes. But does the clinical aspect of the case permit a diagnosis of tabes? In favor of the latter speaks the loss of the knee-jerk and of the Achilles tendon reflex on both sides. On the other hand, we do not find here an involvement of the sphincters of the bladder and rectum, nor symptoms referable to the pupils, to the eye-muscles, or to the eye-grounds. Besides, the characteristic course of the disease,

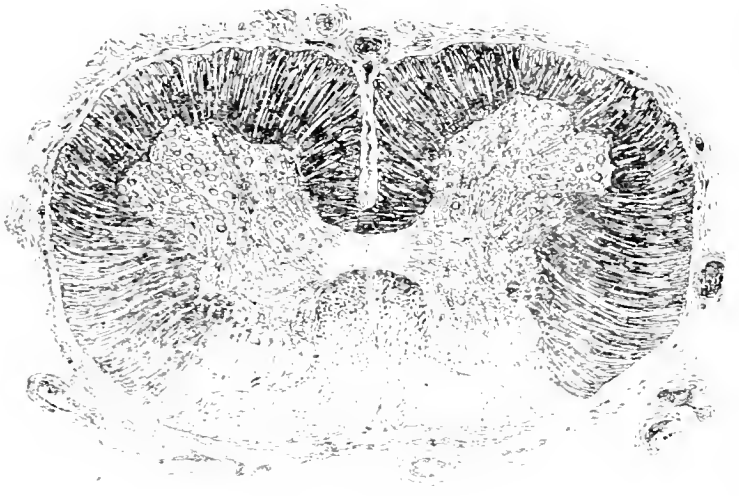

FIG. 2.—Lower lumbar segment of the cord; degeneration of the posterior columns; thickening of the pia mater and of the vessel walls; Wiegert stain.

viz., the long and successive development of preataxic, ataxic, and terminal periods of the malady, is entirely wanting in this case. The disease was confined exclusively to the lower extremities, and very early in its course they became rapidly disabled. It is true that in tabes a division of the course of the disease is arbitrary, as the evolution of the affection is very variable from individual to individual. In certain tabetics some symptoms make their appearance before ataxia, in others only after the latter is definitely established. In the case under discussion there was no other symptom, but a paraplegic condition of the lower limbs. As is well known, paraplegia is an extremely rare condition in the course of tabes, unless as such is considered the motor disability which is observed in very advanced cases. It is remarkable that this extreme motor disability was almost complete in the patient from the beginning of her affection and remained unaltered during the remaining few years of her life. A genuine flaccid paraplegia, such as is seen in myelitis, was evident during the entire course of the disease to the exclusion of other symptoms of tabes, such as Argyll-Robertson pupil, optic neuritis, radicular pain in the limb, and disturbed function of the sphincters of the bladder and rectum. Pathologically, the affection proved to be that of tabes, but clinically it could not be considered typical of the classical tabes, as not only some of the constant and characteristic symptoms were present, but also the course of the disease did not correspond to that of the syndrome, originally described by Duchenne. Besides, there was no history of specific infection, and the Wassermann test repeated at various intervals was invariably negative.

Have the marked deformity of the spinal column and the thickening of the lower dorsal vertebræ any influence on the development of the posterior sclerosis? Unfortunately, permission could not be obtained for the removal and examination of the affected bodies of the vertebræ. Nevertheless, the thickening of the bony tissue can reasonably explain the pathological condition of the cord. It is probable that an initial inflammatory condition of the vertebræ led gradually to its thickening and subsequently to an irritation of the posterior nerve roots and of the meninges with the result of a final involvement of the posterior columns of the cord.

The severe lancinating pain in the epigastrium, from which the patient suffered during the four years of her illness, are explained by the diseased condition of the meninges and of the roots. As the affection was confined only to those structures and only to one segment of the cord, other characteristic symptoms of tabes were entirely absent. It is therefore with a mechanical production of meningitis and radiculitis with a subsequent sclerosis of the posterior columns that we are dealing here, but not with a specific affection in which the meninges, roots, and posterior columns of the cord are primarily attacked by a special agent which, we know now, is of syphilitic nature.

The slight anemia the patient presented, viz., 85 per cent. of hemoglobin and 4,000,000 erythrocytes, can hardly be taken into consideration in the search for an explanation of the pathological findings. In the first place all the cases reported show that the anemia must be quite pronounced and associated with actual blood destruction in order to produce degeneration of the white matter in the cord. In chlorosis, for example, cord changes do not occur. Secondly, the process of degeneration in the cord associated with pernicious anemia is usually not

systemic in character; it is only quasisystemic (see A. Gordon: "Histological Changes of the Spinal Cord in Pernicious Anemia." *New York Medical Journal*, July 3, 1909, p. 8). Besides, in none of the cases reported the posterior columns alone were involved. Either the lateral columns are associated in the pathological process or else the degenerative changes are diffuse.

An analysis of the symptoms of the evolution of the disease of the morbid condition of the vertebræ and the spinal cord, finally of the unusual paraplegic condition of the extremities from the beginning until the end, and especially of the absence of the majority of the cardinal symptoms of the classical locomotor ataxia, naturally leads to the conclusion that we are dealing here with a degeneration and sclerosis of Goll's columns of a spinal cord in an individual who was not tabetic. The rarity of such an occurrence warranted my placing the case on record.

I wish to thank Dr. Boyer for the privilege of examining the spinal cord. The patient was in his service at the Stetson hospital during the last two or three weeks.

THE TREATMENT OF SCIATICA BY PERINEURAL INFILTRATION.*

BY WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

NEUROLOGIST TO THE LEBANON AND HARLEM HOSPITALS.

THIS method of treatment for sciatica was first introduced to the medical profession by Dr. J. Lange of Leipsic in an article read before the Congress for Internal Medicine held at Wiesbaden April 15, 1907. It consists in the injection of large quantities of fluid under high pressure directly over the sciatic nerve or in its immediate vicinity.

Lange claimed that the favorable results obtained were entirely due to the mechanical action of the fluid in loosening, stretching, or breaking up adhesions in the neighborhood of the nerve. He reported fifty-six cases, 65 per cent. of which were completely cured. In 1909 Dr. D'Orsay Hecht of Chicago described this method in detail and suggested several valuable modifications and improvements in the technique. (*Journal A. M. A.*, Feb. 6, 1909.) During the last year I have adopted the plan as outlined by Dr. Hecht with the most gratifying results.

Sciatica, whether a symptomatic neuralgia or the result of a perineuritis, is admittedly a very intractable and painful affection, often persisting for months or longer, under the usual forms of treatment.

After many years of experience with all of the available and conventional remedies I have found, in confirmation of the reports of other clinicians, that the injection of saline solution as herein described is a valuable therapeutic acquisition. From an economic standpoint it is often superior to many other forms of treatment, for, in the majority of instances, it rapidly relieves the pain, and the sufferer is soon enabled to return to his customary vocation. A striking illustration is the case of a man forty years of age (Case I) who had suffered from sciatica for one year. Many drugs and applications had been unsuccessfully utilized at the various clinics and at home. He had been in the general medical service of the hospital for six weeks without relief, during which time he had been confined to bed, unable to move without great pain. Immediately after one injection, he walked from the operating room back to his bed, a distance of 100 feet. The relief from pain was prompt, improvement in his general condition was rapid, and in the course of ten days he walked out of the hospital perfectly well. He has remained free from pain, a period of one year having elapsed since the first and only injection.

In mentioning to physicians the successful and brilliant results obtained from this form of treatment, I have often been asked if alcohol injections would not be preferable, as in trifacial neuralgia. The reply to this question is that alcohol promptly produces motor paralysis and degeneration of the nerve. Such cases are well known, a number having been reported, and one has recently come under my observation in which the paralysis has lasted a year and has not yet shown any signs of improvement. For these reasons the use of alcohol in such cases has been discontinued as unsafe. In the treatment of trifacial neuralgia, however, we are dealing with a nerve which is almost purely sensory in function, and it is our aim to produce an acute degeneration in the nerve with the accompanying sensory paralysis.

The earliest period of the disease in which I have had the opportunity of using this remedy was in Case XIV, duration one week, and in Case X, of two weeks' duration. Both of these patients recovered promptly.

In these acute cases the relief must have been due either to a blocking of the sensory impulses or to the pressure and absorption of the fluid producing some change in the circulation and nutrition in the perineural structures. It would be too early in the course of the trouble to assume that the pain was caused by the presence of adhesions.

During the application of the treatment the patient should lie on the abdomen with the legs fully extended and the feet projecting beyond the edge of the table. A firm pillow is placed under the lower part of the abdomen in order to favor relaxation of the gluteal muscles. For the purpose of locating the nerve the following measurements are made: A line is drawn from the sacrococcygeal articulation to the postero-external border of the great trochanter; at the junction of the inner one-third and the outer two-thirds of this line is found the spine of the ischium. One inch to the outer side of this point we locate the point of puncture. An area of the skin about 4 cm. in diameter is then painted with iodine, the point of puncture being in the center. The syringe used is all metal holding 60 c.c. It has a slip tip which allows the needle to fit the barrel directly. The needle is of steel, 12 cm. long, with a caliber of 1.5 mm., and provided with a sharp point, which is protected by a dull-tipped stylet projecting 1 mm. beyond the point of the needle. In puncturing the skin and subcutaneous tissue the stylet is withdrawn beyond the cutting edge. It is then replaced and the needle pushed in perpendicularly. When the sciatic nerve is reached, at a depth ranging from 6 to 12 cm., the patient may feel either a sharp pain radiating from the point of contact to the popliteal space or down to the foot; or a sharp pain in the corresponding heel; or there may occur a jerking movement of the leg; or a sudden twitch in the calf muscles. Some patients complain only of diffuse pain in the buttock. It is unnecessary and unsafe to penetrate the nerve sheath. The stylet is then removed. The syringe having been filled with sterile normal saline

solution at a temperature between 95° and 100° F., the fluid is slowly injected. The quantity used is from 80 to 120 c.c. The needle is quickly withdrawn, the iodine washed off with alcohol, some collodion applied over the point of puncture, and this is covered with a small strip of sterile adhesive plaster.

The patient is then instructed to lie abed and rest for twelve to twenty-four hours. No anesthetic is required. In the administration of this treatment strict aseptic precautions are absolutely essential.

Soon after the injection some aching pain with a sensation of heaviness and numbness in the limb usually follows, but this lasts only a short time. In some cases the sciatic pain in the thigh disappears within twenty-four hours, but the patient complains of pain continuing in the leg in the course of the peroneal nerve. This is often promptly relieved by an injection of 10 to 20 c.c. in the region of the nerve at the head of the fibula. The interval following the first injection, before another is given, will vary according to the degree of relief obtained. I have been in the habit of waiting from thirty-six hours to one week before repeating the injection. I have given more than sixty injections without encountering any unpleasant symptoms. Under proper technique and strict asepsis it has proved an absolutely harmless procedure.

Up to December 26, 1911, I have treated twenty-five patients with sciatica by this method, with the following results: Thirteen cured, ten improved, and in two there was no improvement. There were twenty males and five females. The duration of the disease varied from one week to two years.

In nine of these who were cured perineuritis was assumed to exist, for the three cardinal symptoms were present, *i.e.* pain on extension of the leg with the thigh at a right angle with the abdomen; tenderness and pain on pressure at the sciatic notch and over the trunk of the nerve, and diminished or lost Achilles reflex.

Two were cured after 1 injection, the duration of the disease being 4 months, 12 months; three after 2 injections, duration, 2 weeks, 8 months, 10 months; two after 3 injections, duration, 7 months, 18 months; two after 4 injections, duration, 4 months, 18 months.

The four others who were cured did not show such pronounced signs of neuritis. Two received 1 injection, duration, 1 week, 12 months; one had 2 injections, duration, 14 months; one had 5 injections, duration, 15 months.

In ten the improvement was pronounced. Although complete relief was not obtained, nearly all of these patients were enabled to resume their former occupation. Three received 1 injection, duration, 3½ months, 6 weeks, 7 weeks; three had 2 injections, duration, 3, 6, and 8½ weeks; three had 3 injections, duration, 8 months, 6 months, 5 weeks; one had 5 injections, duration, 2 years.

In two patients there was no improvement. Each received a single injection. One discontinued treatment as she lived out of town, and the other was a case of tuberculous disease of the hip-joint associated with sciatic pain.

145 West Seventy-seventh Street.

ADENOIDS IN SCHOOL CHILDREN AND THEIR EFFECT ON THE GENERAL SYSTEM.*

By G. B. TAYLOR, M.D.,

CAMERON, TEX.

In 1868 Meyer of Copenhagen first drew the attention of the medical profession to the clinical importance of adenoid growths. Patients receive the greatest immediate and permanent relief by the removal of the growths. An incalculable number of individuals at this present moment are useful members of society, who, but for this operation, would have become permanently deaf, and besides would have suffered great inconvenience and discomfort. Those who have been neglected frequently betray in their faces ample evidence of the permanent mischief done by adenoid growths in their childhood.

Adenoids are found in varying degrees of frequency in at least three parts of the world, namely, Europe, America, and Asia. A warm climate seems to be less favorable to their development than a cold one. Along the equator, where the temperature never varies between 75° F. to 80° F., and where it is dry and mountainous, only 5 out of 717 school children were found to have adenoids, and not one out of 100 adults who were examined. On the contrary, in Greenland only 16 out of 60 Esquimaux children between the ages of four and twelve were found to be free from adenoids. These growths probably have been recognized from a very remote period of human history. Several ancient Roman statues and busts show evidence of their existence. The numerous likenesses of the famous sculptor,

*Read at the Milan County School Teachers' Institute, October, 1911.

Canova, show the artist with open mouth, narrow nose, and dull, stolid look, and there is further testimony of his being deaf.

Adenoid growths, which are met with at all ages from birth to seventy years, consist of an hypertrophy of the lymphoid tissue in the vault of the nasopharynx, known as the2 pharyngeal tonsil, which is especially well developed in children. It has been calculated that 90 per cent. of children who have enlarged tonsils also have adenoid growths, but adenoid growths are frequently present without enlarged tonsils. Statistics of school children indicate that from 20 to 30 per cent. suffer from adenoids. The greater number of these display no symptoms sufficiently definite to attract general attention. Examination of 13,458 school children in Chicago showed that 5,826, or about 42 per cent., had adenoids.

Energy, ambition, noble impulse, and high ideals all succumb to pain and ill health and are frequently usurped by idleness and vice. Inability to apply themselves comfortably drives multitudes of children from school and thus reduces the intellectual and moral index of communal and national life. A larger percentage than generally imagined possess adenoids. These are a potent menace to hearing, Cavanough of Chicago regarding them responsible for 88 per cent. of deafness. Tydings of Chicago states that in at least 90 per cent. of cases of adenoid vegetation there is involvement of the Eustachian tube with deafness in varying degree. If the deafness is marked and occurs before the child has learned to talk, he will remain dumb; if he becomes deaf at the age of five or six after he has acquired the faculty of speech, he will soon forget how to talk. There is no faculty upon which mental development is dependent to such an extent as upon that of speech. Thought in its higher functions exists only through expression by means of language, of which articulated speech is the most important manifestation. It is impossible for the child to reproduce what he has never heard; consequently two great stimulants are lacking, the power of understanding spoken language and the faculty of expression by means of speech. When to these are added the aprosexia and nervous instability usually present in adenoid subjects one need not wonder at a diagnosis of idiocy or imbecility.

When the deafness is complete after the removal of the primary cause the treatment should be the same as that accorded any other deaf and dumb child. When there is even a slight vestige of hearing remaining it is often possible by persistent and careful effort not only to develop speech, but also to improve greatly the ability to hear. The condition resulting from adenoids may be a slight deafness from middle ear disease, preventing the child from hearing all sounds, except those of a certain pitch of intensity, which he will, of course, reproduce as he hears them, or may be due to faulty subjective audition, the objective hearing being normal. In the latter case he hears words correctly and believes that he reproduces them as heard. His subjective auditory center has become accustomed to receive faulty word impressions, and has lost or fails to develop its power of differentiation. This is dependent upon faulty kinesthesia derived from the peripheral vocal musculature which is impaired by the presence of adenoids. For this reason, after the removal of adenoids, a special course of training directed toward the development of the kinesthetic and auditory word centers is necessary.

The aprosexia resulting from adenoids is probably responsible for more cases of backward and deviated mental development than any other cause. Unable to apply himself to his studies the child soon falls hopelessly behind his classmates, casts about for other means to keep his mind occupied, thereby getting himself into mischief of various kinds, and soon becomes a nuisance to his teacher and to his schoolmates. His school duties becoming hateful to him, he becomes a truant with an enlarged field for his unrestrained activities, and finally coming into conflict with the authorities through his desire for constant change and excitement, ends in the juvenile court and the reformatory. If he is of the phlegmatic type, content to plod without results, to stay where he is put, he becomes the dunce of his class, remaining in the same grade until, either outwearing the overstrained patience of the teacher or outgrowing his seat, he is advanced to the next grade, there to repeat the process. These are extreme cases, but they are to be found in every school and many others less only in degree in every classroom.

The hypoplastic child, fundamentally unstable, and still further handicapped by adenoids, with their attendant train of evils, is prone to respond to an exaggerated degree to faulty environmental influences of all kinds and requires the most careful study and attention to ensure the advancement of which he is frequently capable. Many cases of pigeonbreast and anterior transverse depressions are found in adenoid breathers. There is no doubt that children suffer in health owing to the mucopurulent discharge from the nasopharynx entering the stomach, deranging the digestion, and destroying the appetite. Headaches and other nervous symptoms are not uncommon and are possibly due to pressure on the blood and lymphatic circulation in the nasopharynx owing to the hyperemia that usually results from adenoids. These are undoubtedly a factor in the production of convulsions in young children through imperfect oxygenation of the blood.

W. A. Fisher, ophthalmic surgeon to the Eye, Ear, Nose, and Throat Hospital of Chicago, has drawn attention to the following eye effects, which he believes are secondary to adenoids: (1) Phyctenular conjunctivitis, the most common. (2) So-called weak ulcer of the cornea, the non-inflammatory ulcer, which looks as if a small piece of the corneal surface has been gouged out. (3) Eczema of the cornea. (4) A peculiar irritability or sensitiveness of the retina, so that, in the absence of corneal ulceration and all unusual causes of photophobia, there is considerable difficulty in opening the eyes in a bright light. These troubles are brought about by the lowering of the general health by the extension of the inflammatory process up the nasal duct to the eye, in much the same way that adenoids produce deafness by extension of the inflammation through the Eustachian tube to the middle ear.

Adenoids occur in individuals who present symptoms of hypoplasia resulting either from hereditary or developmental causes. They are factors in retardation by their mechanical action as a source of reflex irritation and as an impediment to the proper development of the cerebral centers concerned in speech. The removal of adenoids is not sufficient in cases of marked defect to bring about restoration to the normal. Special training and the institution of measures directed toward the amelioration of the underlying hypoplastic condition are necessary.

THE TREATMENT OF SIMPLE CATARRH OF THE RESPIRATORY PASSAGES WITH BACTERIAL VACCINES.

By A. PARKER HITCHENS, M.D.,

GLENOLDEN, PA.

THE theory explaining the beneficial effect following the administration of bacterial vaccines supposes that the invaded tissues are weaker than normal in their resistance to the growth of bacteria. This is due primarily to conditions which permit either local multiplication or increased virulence of the bacteria, or both; and secondarily to the local and general effect of the products of the bacterial growth. This effect is evidenced by a diminished antibacterial power of the blood and tissue-juices generally, and to a still weaker condition of the fluids locally. In order to bring about recovery from infection, it is necessary to improve the antibacterial power of the blood, and to bring this blood of better quality in as close contact with the infecting elements as possible, and in as great an amount as possible.

It is a fundamental principle of bacterial vaccine therapy that, unless the blood of improved quality is able to reach the focus of infection, improvement from the use of bacterial vaccines may not be expected; and that, if the condition under treatment is one in which the body fluids may be made to flow freely through the diseased area, improvement should be uniform and rapid.

When we consider the pathogenesis and pathology of simple catarrh of the respiratory passages we see immediately that this is a disease which theoretically should be ideally amenable to treatment by bacterial vaccines. The etiology and pathogenesis of simple acute rhinitis are not well understood. Various organisms have at various times been credited with being the specific cause, but there is little uniformity of opinion in this regard, and the idea that there is a "cold germ" has been long abandoned.

As in practically all other infections, there are predisposing causes of lowered general resistance, such as diminished vasomotor tone due to anemia and the various dyscrasias. The more immediate influences which are followed by a disturbance of tonicity of the mucous membranes result first in a local anemia, and then a congestion of the mucous membranes; these are generally mentioned as the causes of common colds. Such influences are draughts, especially on those parts of the body closely connected with the nerve supply of the nasal mucous membrane through the sympathetic system.

Chilling, draughts, wet feet, etc., are the traditional causes of acute coryza, and few medical writers are willing to risk an opinion which, when translated into common English, says more. To the bacteriologist, however, these influences, resulting in a hypersecretion of mucus, merely supply a culture medium upon which the bacteria commonly present are able to grow very rapidly; and, as the culture medium is so favorable, increased virulence is not improbable. Were it not for the development of the bacteria the vasomotor equilibrium would soon be reestablished and a return to normal conditions would be a matter of only a few hours. This would be the case even though a suspension of the insensible perspiration of the chilled part of the body should have caused the nasal mucous membrane to attempt compensatory labor, resulting in the secretion of an abnormal irritating mucus.

The copious watery discharge characteristic of acute coryza is an admirable culture medium for the growth of the many organisms commonly present in the nose and throat. As a result of the rapid bacterial growth the watery fluid quickly changes its character to a yellowish, purulent, viscid mucus. A vicious circle is now established, the bacteria grow in the mucous secretion and produce poisons which, irritating the membrane, cause it to produce more mucus: mucus—bacteria—toxic substances—irritation—mucus—and so *ad infinitum*. This condition may continue until there is a permanent hyperplasia of the membrane or other pathological change characteristic of chronic catarrh.

If the person afflicted with an ordinary cold is in fairly robust health the cold will last but a relatively short time even without treatment. If treatment is instituted the most successful is that directed against the secretory function of the mucous membrane and such drugs as opium and atropine are used. And they may be supplemented by methods to deplete the fluids of the body and restore the vasomotor equilibrium. Local antiseptics are sometimes recommended. If the cold has run on to the subacute stage, these lines of treatment are dropped and alteratives are indicated. Until recently such methods of treatment have been almost entirely empirical or their secondary effects have been erroneously credited with beneficial influences. That they have a reasonable scientific explanation we see as soon as we apply the theories resulting from a study of bacterial vaccine therapy to the phenomena of ordinary catarrh.

I think that the determining factor in simple catarrhs is a bacterial infection of the mucous membrane and its secretion. It is primarily a surface-infection, and the bacteria with their poisons are present in such quantities that they are able to overcome the resistance of the tissues. The methods used to dry up the secretions are efficacious only in the early stages of the cold, and they act really by removing the culture-medium. Frequently such methods merely postpone the attack. Revulsive measures such as purging and sweating reestablish the nervous equilibrium, relieve the local stasis, and restore a more vigorous and healthy circulation locally, thus using the antibacterial power of the blood to the best advantage of the local tissues. Local antisepsis is obviously of little value either theoretically or practically. Later, when the cold has reached the subacute stage, the proper treatment is to apply measures to improve the quality of the blood by building up the general health. Medicinal tonics and personal hygiene are commonly used to accomplish this. What actually happens is that the normal resisting power of the blood is restored, and as it nourishes the overworked cells it is able to offer them greater assistance in neutralizing the toxic substances attacking them; when this happens the cold rapidly disappears. If it is possible for the patient to take a vacation the locality selected should be one free from street dust and other sources of reinfection.

With these facts before us the rationale for the use of bacterial vaccines in catarrhs of the respiratory passages is plain. The proper bacteria are injected in suitable dosage beneath the healthy skin. The usual reaction takes place, resulting in the production of specific antibodies which find their way into the blood and tissue juices. There is no difficulty in bringing the blood of better quality to the infected surface (except possibly in the hypoplastic stage of chronic catarrh) on account of the characteristic blennorrhea which constantly demands more

fluid. The ideal condition is present. The focus of infection is being constantly flooded with fresh lymph, and much of that used up does not get back into the body, but is thrown off.

The kind of bacteria to be used as the vaccine is important. A few years ago many attempts were made to determine the particular organism responsible for colds. We now believe that there are many germs pathogenic to the mucous membrane of the respiratory passages, and that any one of them, or a combination of any or all, may be responsible. That different types of colds are caused by different bacterial species there can scarcely be any doubt. Further study may identify the exact relationship. It has been said that certain individuals are more susceptible to one type than another. However this may be, the thought suggested itself to me long ago that the attempt to immunize persons against common colds by the use of special single vaccines was inadequate. Each individual is probably at periods susceptible to the whole list, and if we wish satisfactorily to immunize him against catarrhs we should immunize him to all the more common germs known to be pathogenic to the mucous membranes. And until such a plan is adopted immunization against colds will be inadequate and unsatisfactory.

With this conception of the pathogenesis of and recovery from catarrh in mind, it was decided to make a mixed vaccine and use it for the treatment of an acute catarrh in a person who had had chronic catarrh for twenty years. The results were so encouraging that similar treatment has been started in several other persons suffering with acute and chronic catarrhs, and I am offering this preliminary communication as a suggestion for the routine specific treatment of acute and chronic catarrh.

The vaccine used contained in each cubic centimeter the following bacteria, which were chosen as representing those species most frequently found in the infected respiratory mucous membranes:

Staphylococcus aureus	150 million.
Staphylococcus albus	150 million.
Streptococcus	50 million.
Pneumococcus	50 million.
Members of the *Micrococcus catarrhalis* group.	50 million.
Members of the bacillus of Friedländer group	50 million.

In robust persons in the chronic stage of the disease the initial dose of this vaccine has been from 0.25 to 0.5 c.c., administered subcutaneously, generally about the insertion of the deltoid muscle. The subsequent doses have been given at five-day intervals, and the amount has not been increased above 0.5 c.c. A few persons receiving the initial dose during the acute stage were given 0.25 c.c., and this dose was repeated at shorter intervals.

It has been noted that on the third or fourth day after the injection of the vaccine the absence of the usual secretion makes the nose feel very dry. In such conditions an oil spray has been agreeable.

Following the injections there are the usual redness and slight swelling at the point of injection. A few patients have had slight symptoms of a negative reaction on the day following the injection, but this has in no case been severe.

In conclusion, it is my belief that the treatment of catarrh of the respiratory passages by a mixed bacterial vaccine is simple, direct, and specific. To get the best results the vaccine should contain those organisms most commonly pathogenic to the respiratory mucous membranes. The treatment must necessarily include the removal or other surgical treatment of obstructions and growths of various kinds between attacks. It is certain that a number of patients will be found who will not be benefited beyond a certain point by the mixed vaccine. In such cases the mucus should be examined bacteriologically, and the mixed vaccine supplemented by the other pathogenic organisms found.

The Bordet-Gengou Reaction in Scarlet Fever.—J. A. Berannikov, employing as antigen extracts made from the organs of patients that have succumbed to scarlet fever, and from the secretions and excretions of scarlet fever patients, obtained the Bordet-Gengou reaction in scarlet fever cases from two to forty days after the beginning of the disease.—*Casopis Lékaru Ceskych.*

Examination of Butter in Human Milk by Centrifugation.—E. Pleuchu and Robert Rendu believe that centrifugation is the best method of estimating the amount of fat to be found in human milk, and far more correct than the method of chemical estimation. They base their statement on 3,450 examinations of milk made in forty-six nursing women on 530 consecutive days. These women were chiefly primiparæ between the ages of twenty and twenty-five years, staying in the Ramond Nursery. Although these results are not absolutely correct they are sufficiently so for all practical purposes. The authors found that there are daily variations in the quantity of fat, and this shows how incorrect a single estimation may be. In general there is an average of 34 grams of fat per liter, the specimen being taken at the beginning of each nursing. The influence of multiparity, the age of the nurse, and the duration of lactation are quite variable. The influence of feeding, of galactogogues, and of menstruation are almost nil. There are four factors that do affect the amount of fat; these are the quantity of milk secreted, the larger the amount of milk the smaller the amount of cream; the time of nursing, the morning milk being richer in fat than the evening; the phase of nursing, the first milk drawn being richer than the last; and the asymmetry of the breasts, the smaller breast giving the greater amount of cream; milk too rich or too poor in cream may cause diarrhea, especially in the prematurely born.—*Lyon Médical.*

Radiotherapy and Glandular Atrophy in the Treatment of Fibromata.—F. de Courmelles believes that the penetrating affect of the *x*-rays is shown by the atrophy which they cause in the ovaries, mammary glands, and lymphatic glands. He finds the *x*-rays of the greatest value in the treatment of fibroids. They relieve the hemorrhages, make the intervals between the menstrual periods longer, lessen the pain and pressure symptoms, and reduce the size of the tumors, in some cases causing them to disappear entirely. *X*-rays should not be used in the treatment of vaginal fibroids, of those undergoing malignant degeneration, and of cases in which the symptoms are rapidly culminating, and must be treated more rapidly than can be done by means of the rays. With proper technique, the employment of penetrating rays, the use of a proper filter, and the separation of the treatments by proper intervals there will be no bad symptoms, such as burns, and only a tanning or a slight erythema of the skin over the abdomen, and epilation of the hairs. In disorders of menstruation with hemorrhage, especially at the menopause, this treatment is valuable. In cases in which sterilization is necessary the use of the rays will avoid a mutilating operation. In cases of ovarian pain not due to tumors the pain may be relieved by this method of treatment.—*Gazette de Gynécologie.*

JOSEPH LISTER.

ONE of the greatest men of the nineteenth century—of the world in any age, if we may measure a man's greatness by the lives he has saved rather than by those he has destroyed or by the misery he has caused—has gone. On Sunday last, at his home in London, Baron Lister—Sir Joseph Lister was the title by which he was known at the height of his professional activity—died at the ripe old age of 84 years and 10 months. He was born in Essex, April 5, 1827, and educated in medicine at the London University. He passed his early professional life in Scotland, being assistant surgeon to the Edinburgh Royal Infirmary in 1850, professor of surgery at Glasgow University in 1860-1869, and professor of clinical surgery at Edinburgh University in 1869-1877. In the latter year he was called to London as professor of clinical surgery at King's College, and retained this chair until 1893 when, broken by the death of his wife, a daughter of James Syme, the celebrated Scottish surgeon, he retired from active work.

It was while he was professor at the University of Glasgow that Lister devised his system of antiseptic surgery, to which he was led by a study of Pasteur's work on fermentation and putrefaction. He applied to animal tissues the principles enunciated by Pasteur in the case of plant derivatives; he showed that inflammation and suppuration were of the same nature as fermentation and putrefaction, and reasoned that, as fermentation could be avoided by preventing the access of germs so might inflammation and suppuration be avoided by the same means. The various steps by which this object was obtained and the gradual evolution of the present day asepsis from the original antiseptic surgery with its carbolic spray have been followed by many surgeons not yet old, and are known to all, yet it requires an effort, even for those who have lived the history of the development of aseptic surgery, to picture the difference between the modern surgical ward and that of less than forty years ago. Who knows to-day of hospital gangrene? Who sees the strong man brought to death's door by the drain of prolonged suppuration from an operation wound, which heals now with barely a drop of moisture on the dressings? Who remembers the time when to open a knee-joint was to commit murder, or to cut into the abdominal cavity required more courage than most surgeons, even the most intrepid, could boast of? Yet such things were within the lifetime of many now living, and they have been relegated to the limbo of the spinning wheel, the stage coach, and the flintlock pistol by the genius of Joseph Lister.

Many years ago, on the occasion of a celebration at which Lister was honored by a great assembly, the American Ambassador, Mr. Bayard, said: "My Lord, it is not a profession, not a nation, it is humanity itself which, with uncovered head, salutes you." So now, it is not medicine, not Great Britain, but the world which mourns not his death, for he himself welcomed it, but gives thanks for his life and for the immense boon he conferred on mankind.

HOSPITAL SOCIAL SERVICE IN NEW YORK.

WHEN in 1791 Sir William Blizzard of the London Hospital organized a society for the purpose of improving the home conditions of hospital patients and of following up the patients who have been discharged from the hospital, he planted the seeds of a philanthropy which attracted little notice until after the lapse of a century it took vigorous root on American soil. The Massachusetts General Hospital provided the nursery for this new growth, and, since the first report on this phase of hospital activity by the Massachusetts institution in 1905, the service has been established in between forty and fifty hospitals in different parts of the United States. Miss Mary E. Wadley, Executive Secretary of Bellevue and Allied Hospitals, who has had charge of social service in Bellevue Hospital, points out the above facts in an article on hospital social service in the *American Journal of Nursing*, November, 1911. She states that the chief aims of this service are (1) to aid the physician in his diagnosis and treatment by the investigation and relief of social conditions; (2) to make available the philanthropic resources of the community and to coordinate medical agencies in restoring a patient to complete physical efficiency; and (3), not least in importance, to carry the educational influence of the hospital to the homes of the community.

In Bellevue Hospital a strong advisory board has been formed to aid the development of the service. This committee includes the representatives of the governing bodies of the hospital—the trustees, medical board, dispensary board, managers of the training school, the general medical superintendent of the hospital, the general superintendent of nurses, the chairmen of special subcommittees, with the head worker as executive secretary. The enthusiasm that has attended the enlistment of many individuals and of many phases of hospital activity during the five years since social service was established at Bellevue Hospital has rendered possible an extraordinary extension of this form of enlightened philanthropy.

The division of labor that is necessarily associated with any large undertaking is strikingly seen in the multiple phases of activity that form part of Bellevue's Social Service Bureau. Patients who are discharged as cured but who need after-care are placed in convalescent homes; they are provided with clothing and with railroad fare if neces-

sary, and efforts are made to restore these patients afterwards to self-support. Incurables, defectives, epileptics, deaf-mutes, soldiers, and the aged are placed in permanent homes. Some individuals may require reformatory care or temporary homes. Home visits are made to investigate the domestic environment of patients. Temporary care is secured for children whose parents are in the hospital; tuberculous patients are specially provided for; and aid is secured for destitute families by reference to relief societies. In the case of children a system of follow-up work is carried out, together with instruction in home and individual hygiene. Special class work is provided for cardiac patients. Among the many other activities of the Social Service Bureau may be mentioned the securing of employment, legal aid, and loans; the accompanying of patients to homes, trains, and court; the transmission of messages to relatives and friends; the provision of dental treatment; the investigation of the identity of unknown patients; and cooperation with other social workers regarding patients in the hospital.

The personnel of this most comprehensive scheme of social relief includes in addition to the special committees a general welfare division with two salaried workers; a tuberculosis division with eight salaried workers; a child-welfare division with three salaried workers; a maternity division with one salaried worker, and a Jewish division with one salaried worker and volunteers. There is also one salaried worker for each of the allied hospitals, Harlem, Fordham, and Gouverneur. Among the classes of patients provided for are the homeless, immigrants, boys, crippled children, deserted or unmarried maternity cases, prisoners and attempted suicides, alcoholic and drug habitués, neurasthenics, and the insane.

One cannot better epitomize the aims and methods of hospital social service than by quoting the language of Miss Wadley: "The great awakening sense of social responsibility which is spreading over the world in these days has reached the hospitals and is creating a new order of things there. Now when the hospital, by medication, has relieved the cardiac's attack, for instance, it looks into his home conditions and the nature of his employment. If we find that his home is at the top of a tall tenement, we see the wife or mother before his return home, and persuade her to look for the lightest, airiest rooms she can find on the ground floor, and we shall not stop with that advice, but if she has not the means for moving we will help her to secure them. We must see the case through to a practical conclusion, for again half measures are a sheer waste. If the patient's former employment requires great physical exertion, our duty is not fully done until we have seen him installed in more suitable work and supplied with good living rations until he has gotten fairly to earning. We may not need to do all these things for him ourselves, but we must see that they get done. Finally, we should urge him to attend our weekly evening class for cardiacs, that we may continue our oversight of him. Maladjustment to home conditions, monotony —perhaps of the all-work-and-no-play kind— worry, overwork, or lack of work, poor cooking, or insufficient food, cheerless or unsanitary surroundings, hidden poverty, or unhygienic habits— often to help a patient to change some one of these conditions will be to touch the button that will entirely transform the sick person into a well and normal one."

NATIONAL CONTROL OF QUARANTINE.

Among the Society Reports in this issue of the Medical Record our readers will find a full presentation of the arguments in support of the transfer of the New York Quarantine from State to Federal control, advanced at the meeting of the Academy of Medicine held the first of this month. That an agitation in favor of this obviously necessary move was not begun earlier is only an evidence of the implicit trust which the medical profession of the State and the country has reposed in the skill and integrity of Dr. Doty. While Dushkind and Bulger last summer were eagerly inviting the testimony of a few ignorant immigrants in their futile attempt to discredit the quarantine administration, they failed to note the fact that the sanitarians and physicians of the entire country were content to leave what is manifestly a national task in the hands of a State official simply because he was discharging it so well. This silent testimony of an army of creditable and competent witnesses was wilfully ignored by the prejudiced investigators and by the Governor as well. But the latter has overshot the mark and made clear why neither he nor any other governor of this State should have anything to say regarding the New York Quarantine. If Mr. Dix's charges are true then it is fearful to think of the peril to which the country has been exposed these sixteen years through the incompetence of the State quarantine officer, and it is high time the national government placed its own officers in charge at the Port of New York. On the other hand, if the charges are not true, as of course they are not, the fact is now patent that the country cannot permit the most vulnerable point in its sanitary defences to be exposed to the maladministration of any incompetent or inexperienced man the politicians may direct the Governor to appoint.

No doubt Mr. Dix is sorry now that he took such a roundabout way of trying to get rid of Dr. Doty. If he had simply appointed a new quarantine officer, without the farce of an investigation, the act would probably have passed nearly unnoticed and the Governor's position would have been impregnable from the spoilsmen's point of view. But now he has focused the attention of the whole country on quarantine and any move that he makes will be closely watched. He did not dare to make an outrageously bad appointment, and has done as well as he could under the circumstances. There was but one man of all those mentioned as candidates for the place who had had any experience in the work, and him the Governor was apparently not permitted to appoint. At the present writing the appointment of Dr. O'Connell has not been confirmed by the Senate; whether it is or is not, the situation will not be changed. The only argument in favor of State

control is the $12,500 salary of the health officer, and that is an argument that appeals to only one physician in the State and to none outside of it.

VACCINE TREATMENT OF PERTUSSIS.

In 1906 Bordet and Gengou described an influenza-like bacillus which they believed to be the cause of whooping-cough. They were able to find it, almost in pure culture, in the bronchial secretions expelled during the paroxysms of the early stages of the disease. Agglutination tests seemed to be of little value in testing its pathogenicity as cultures of the organism early developed spontaneous agglutination. The complement deviation reaction, however, proved to be almost uniformly positive and at present it furnishes the strongest evidence of the etiological relation of the bacillus to this disease. Efforts to produce a serum by the immunization of animals have, so far, been unsuccessful.

Attempts to influence the course of the infection by the use of vaccines have been attended with some slight success. Bächer and Menschikoff (*Centralbl. f. Bakt.*, I. Abt. Bd. 61, Heft 3, p. 218) prepared a vaccine from one of the original strains of Bordet's bacillus and with it treated a series of twenty-four cases. The initial dose ranged from five to twenty million and the subsequent doses, given at intervals of from four to seven days, ran up to 200 million. One-half of their cases were not at all affected by this treatment, while the improvement observed in the remainder could not be ascribed to the effects of the vaccine. They are inclined to believe that the paroxysms are the result of absorption of toxins produced by these bacilli growing on the surface of the bronchial mucous membrane.

In this country Graham (*Am. Jour. Dis. Children*, Vol. III, p. 41) treated twenty-four cases with doses of from twenty to forty million administered every two or three days. Of these seventeen "were apparently benefited by the treatment." Under the circumstances judgment is difficult, but Graham and his associates all seemed to think that this mode of treatment had a real value.

Bächer and Menschikoff found it necessary to sterilize their vaccine by heating at 60° for several hours, a treatment which may have had its effect upon the therapeutic value of the product. Unfortunately Graham gives no details of the manufacture of the emulsion which he used so that exact comparison is impossible. The seriousness of the disease and the fatality attendant upon its frequent complications make one hope that the investigation will be pursued vigorously.

HYPERTROPHIC CIRRHOSIS AND ACUTE YELLOW ATROPHY OF THE LIVER.

Works on pathology describe acute yellow atrophy of the liver as an acute destruction of the parenchyma of the organ, which results in notable diminution in its bulk, the appearance of leucin and tyrosin in the urine, and well-known clinical phenomena. Hypertrophic cirrhosis seems to be in some ways the very antithesis of the first named affection, for the parenchyma is increased in amount, not only the hepatic cells but the bile ducts showing proliferation. In cases of hypertrophic cirrhosis which eventully end in atrophy we should not be surprised to see acute yellow atrophy supervene, but that the latter could develop in the florid period of hypertrophy seems almost a physical impossibility. Nevertheless, at a recent meeting of the Allgemeiner ärztlicher Verein of Cologne (*Münchener medizinische Wochenschrift*, December 26) Auerbach describes a case of this association which, despite its unique character, seems to have been readily diagnosticated during life. The patient was apparently a healthy man of fifty-four years, who in a few weeks developed marked gastric disturbance followed by jaundice, somnolence, and fatal coma. There was no leucin or tyrosin in the urine. The clinical picture was that of icterus gravis, such as is commonly associated with rapid destruction of the liver; but upon autopsy the latter organ was seen to be very large and hard, corresponding to the physical signs. There was nothing to throw light on the intimate nature of the case—no history or evidence of lues or alcoholism. The final chapter cannot be written until after a most thorough histological study, after which the case will, doubtless, be reported in great detail. Nothing seems to have been stated as to the probable duration of the hypertrophy.

STATIC ELECTRICITY IN NERVOUS AND MENTAL DISEASES.

Joseph J. Kindred read before the twenty-first annual meeting of the American Electro-Therapeutic Association a paper on static electricity in nervous and mental diseases in which he pointed out the good nutritional effects of the one-pole currents charging and discharging through the body. In his opinion its stimulating and secondarily sedative anodyne effects, both local and systemic, and its curative action on localized inflammatory areas make it superior to other treatment in many painful conditions such as neuralgia, myalgia, rheumatism, rheumatoid arthritis, gout, and migraine. Tabes dorsalis is amenable to some extent to the influence of these currents, that is to say so far as the relief of the pains, girdle sensations, and bladder complications is concerned. In some mental states the wave current acts as a combined tonic and anodyne. Dementia precox, it is said, has been treated with success by electrostatic methods. According to Kindred, the most brilliant results with the static machine have been obtained in neurasthenia. In concluding the author expressed the view that, if he were compelled to choose between electrotherapy, hydrotherapy, and physiotherapy on the one hand and drugs and all other medical measures put together on the other hand, he would by all means choose electrotherapy and hydrotherapy in the treatment of neurasthenic conditions.

THYMOL IN HOOKWORM DISEASE.

In the issue of the Public Health Reports for December 8, 1911, Chas. Wardell Stiles and George F. Leonard discuss briefly the administration of thymol in hookworm disease. Recently an exceptionally severe case of the disease came under their observation. In order to impair the patient's strength as little as possible the preliminary dose of magnesium sulphate, usually given the evening before the thymol is administered, was omitted, and very small doses of thymol were employed. The results were satisfactory. In several other cases

thymol was administered without [illegible] and hookworms were obtained. Consequently, on theoretical grounds and from practical experience, in cases of severe hookworm disease, the authors feel justified in recommending that the preliminary dose of salts be omitted and small doses of thymol be used for one or more courses of treatment. It is also pointed out that the number of worms obtained in any given case is influenced not only by the size of the dose of thymol, but by the number and position of the worms present and the amount of food in the intestinal tract. The principle upon which the small dose is used is that if numerous worms are present the thymol will reach some of them at least and a case of severe infection can thus gradually be reduced to one of lighter infection.

News of the Week.

Vaccination in Siam.—A letter to the *Sun*, written by Dr. Charles S. Braddock, Jr., late Chief Medical Inspector Royal Siamese Government, is of interest in view of the antivaccination stand taken by the Tammany aldermen of New York. The official report for the city of Bankok, Siam, covering the time from October 14 to December 9, 1911, shows that for the first week of this period there were fourteen deaths from smallpox and that by the last week the number had risen to seventy-four. Dr. Braddock reports that in a single village of Siam he has seen as many as fifteen or twenty children totally blind from the result of this disease. In the epidemic of 1902 in the north of Siam as many as 75 per cent. of all unvaccinated children under the age of five years died from the disease. The adults were immune because they were the survivors of a previous epidemic and had had the disease. At the present time the Government of Siam is endeavoring to vaccinate all the people, the king and queen having set the example by being vaccinated. In the village of Tatchin an epidemic broke out some time ago and before the officials of the government were notified there were 100 deaths from the disease. The entire population of the village was vaccinated and since that time there has been practically no smallpox there.

Vital Statistics of New York State for 1911.—According to the annual report of Dr. Eugene H. Porter, State Commissioner of Health, which was presented to Governor Dix on February 6, there were 2,002 fewer deaths reported during the year 1911 than during 1910. The death rate per 1,000 population was 15.5 as against 16.1 for 1910, the urban rate being but little more than the rural. The births exceeded the deaths by 75,288. There were about 90,000 marriages, or 5,000 more than for the previous year. Epidemic influenza has been the means of reversing the incidents of mortality so that the winter mortality has been higher than the summer. Pulmonary tuberculosis caused 14,170 deaths last year, about the same as in 1910. For the entire period of the last twenty-five years 11 per cent. of the deaths have been due to tuberculosis. Cancer caused 8,000 deaths, whereas in 1891 it caused only 3,000. The death rate from typhoid fever was the lowest ever recorded, 14 per 100,000 population. There were about 1,000 more deaths from accidents than in 1910.

Death Rate from Meningitis in Dallas, Tex.—According to Dr. Sophian of the New York Health Department, who has been assisting in the fight against cerebrospinal meningitis in Texas, the death rate from the disease in Dallas has been 44 per cent. However, since the treatment with serum was begun, the mortality among children has been reduced to 10 per cent. and among adults to from 10 to 15 per cent.

Yellow Fever in Guayaquil.—According to despatches received from the cruiser *Maryland*, an epidemic of yellow fever is imminent in Guayaquil. General Plaza, the commander of the Federal troops, who quelled the recent revolution, has been stricken with the disease. Officers of the State, War, Navy, and Treasury departments, as well as the officials of the Canal Zone, insist that this port, which is said to be the plague spot of the west coast of South America, be cleaned up. The United States has indicated a willingness to aid Ecuador in the matter as that republic has shown an inability to perform the task.

Bureau of Public Health and Marine-Hospital Service.—A board of commissioned medical officers will be convened to meet in Washington, D. C., Monday, April 8, at 10 o'clock, for the purpose of examining candidates for admission to the grade of assistant surgeon. For further information, or for invitation to appear before the board of examiners, address "Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C." Upon appointment the officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. Assistant surgeons receive $1,500, passed assistant surgeons $2,000, and surgeons $2,500 a year. The tenure of office is permanent.

The Hunting of an Alleged Leper.—Poor John R. Early, who frightened the health officer of Washington, D. C., a couple of years ago, was shipped to New York in a freight car, and acquitted of the crime of leprosy by the Society of Medical Jurisprudence, through the efforts of Dr. L. Duncan Bulkley, is again enduring persecution—this time in the State of Washington. He recently bought a small ranch near Tacoma and undertook to earn his own living and mind his own business as a farmer. But the health officers found him and now propose to erect a high fence around an acre of ground on which his house is built and so protect the otherwise defenceless community. Leprophobia in health officers is a cruel disease—cruel to their innocent victims.

The Wassermann-Ehrlich Cancer Remedy.—Professor Ehrlich, who is more fond of fantastic drug names than is the Council on Pharmacy of the A. M. A., has christened the new eosine-selenium combination, with which he claims to cure mouse cancer, "nigrosin." Concerning this remedy, Dr. Kiliani of this city, at present in Berlin, is quoted in a wireless despatch to the *New York Times* as speaking most enthusiastically of its therapeutic possibilities. From his private observation of their work, he says, he feels safe in expressing the opinion that the discovery of this remedy is one of the most stupendous achievements of modern science. He believes that the problem of cancer treatment may be considered solved and thinks it most probable that within a comparatively short time the treatment of human cancer will enter upon an entirely new phase. The theory of the action of the remedy is that the selenium seizes upon the oxygen necessary for the rapid growth of the cancer cells, while the eosine, being carcinotropic, acts chemotherapeutically upon these cells.

For a Liberal Interpretation of the Nurse Practice Act.—The Public Health, Hospital, and Budget Committee of the New York Academy of Medicine at its last meeting unanimously adopted the following resolution, subject to the approval of the Council of the Academy of Medicine: "Resolved: That it is the sense of the Committee that any regulations adopted by the State Education Department under the Nurse Practice Act, should not be so formulated, interpreted, or applied as to prevent the training in properly equipped hospitals of a sufficient number of pupil nurses to meet the public demand for trained nursing service."

The Janeway Library of Columbia University. At a meeting of the trustees of Columbia University, on February 5, it was announced that Dr. Theodore C. Janeway, Bard Professor of the Practice of Medicine, had presented the trustees with the valuable medical library bequeathed him by his father, Dr. Edward C. Janeway, to be the departmental library of the department of the practice of medicine. The library consists of about 1,500 bound volumes, including complete sets of many of the most important clinical and pathological journals, and about 2,500 unbound monographs, journals, and pamphlets. It was also announced that Mrs. Russell Sage had given $25,000 to establish the E. G. Janeway Library Endowment Fund for the Medical School.

Colonel William C. Gorgas, U. S. A., chief sanitary officer of Panama Canal, has accepted the election to the office of third vice-president of the National Drainage Congress, which will meet in New Orleans April 10 to 13.

Dr. S. Weir Mitchell of Philadelphia attended the dinner with the University of Pennsylvania alumni at the Waldorf-Astoria and his name was put on the cup of honor which the New York alumni are keeping for those who have cast singular distinction on the university.

Dr. A. Jacobi spoke at the opening of the new Hospital for Children in Boston at the Boston Dispensary February 7. What has been erected will be provided with special facilities for laboratory work.

For Charity.—The will of Newman Cowen leaves the following New York institutions each $500: the Lebanon Hospital, Mount Sinai Hospital, Beth Israel Hospital, Montefiore Home, and the United Hebrew Charities. A concert given by the New York Symphony concert to raise a fund to endow a bed in a hospital in memory of Samuel S. Sanford, a member of the musical faculty of Yale, netted about $5,000. Among the numerous bequests made by the will of Eugene Kelly is one of $15,000 for St. Vincent's Hospital, New York. By the will of the late Mary W. Paul of Philadelphia the sum of $20,000 each is bequeathed to the Episcopal Hospital and the Pennsylvania Hospital, $1,000 each to the Children's Hospital and the Pennsylvania Epileptic Hospital at Oakbourne, Pa., and $500 to the Philadelphia Orthopedic Hospital.

Harvey Society Lecture.—The ninth lecture of the present course of Harvey Society lectures will be given in the New York Academy of Medicine on February 17, at 8.30 P.M., by Prof. R. H. Chittenden of Yale University. The subject will be "Current Views Regarding the Nutrition of Man." During the lecture there will be on exhibition in Hoosack Hall, a portrait of William Harvey painted by Cornellis Janssens.

Violent Criticism of Salvarsan.—A despatch to the *New York Times* says that in a recent report to the Academy of Medicine of Paris Professor Gaucher stated that many deaths had occurred in France, Germany, and Roumania through the employment of 606, the patients dying in a state of coma after a few injections. He complained of attempts to hush up such fatalities in France, and insisted that the remedy was of slight therapeutic efficacy.

Free Medical Clinic for Milwaukee.—St. Mary's Hospital has been reorganized and a new medical staff appointed of which Dr. James A. Bach is president, Dr. V. T. Hoibrook, vice-president, and Dr. Hans Rhombardt, secretary. Plans have been made for a free clinic which will be in operation in a short time.

Hagerstown Hospital to Move.—At the annual meeting of the Washington County Hospital Association it was announced that the Kee-Mar College buildings which were purchased some time ago and remodeled and renovated for the hospital will soon be ready for occupancy.

South Carolina Passes School Inspection Law. The bill providing for the medical examination of school children and college students as well as of teachers and all inmates of educational institutions by regularly appointed physicians was passed by the Senate of South Carolina on February 3.

Straus Laboratories Incorporated.—An association to be known as the Nathan Straus Pasteurized Milk Laboratories was incorporated in New York State on February 9. The purpose of the incorporation is to demonstrate the value of pasteurized milk and to distribute the same by means of stations distributed throughout the world. The incorporation also proposes to have licensed physicians instruct mothers in the use of pasteurized milk.

The Western Massachusetts Alumni Association of the Medical Department of the University of Vermont at their annual meeting at Springfield, on February 1, elected the following officers: *President*, Dr. C. W. Jackson of Monson; *Vice-President*, Dr. D. M. Ryan of Ware; *Secretary*, Dr. Charles J. Downey of Springfield.

The Oxford County Medical Association, which held its meeting in Ingersoll, Ontario, January 29, elected the following officers: *President*, Dr. Andrew MacKay, Woodstock; *Vice-President*, Dr. McGougan, Thamesford; *Secretary*, Dr. Brodie, Woodstock; *Treasurer*, Dr. Neff, Ingersoll; *Executive Committee*, Drs. F. S. Ruttan, C. M. MacKay, and A. McLay, Sr.

Appointment of a Quarantine Officer.—Governor Dix has sent to the Senate the appointment of Dr. Joseph J. O'Connell of Brooklyn as Health Officer of the Port of New York to succeed Dr. Alvah H. Doty, whose term expired a year ago. Dr. O'Connell was recommended by Mayor Gaynor.

Death of Dr. Hansen.—The death is announced of Dr. Gerhard Armauer Hansen of Bergen, Norway, the discoverer of the lepra bacillus. Dr. Hansen was born in 1841 and for many years was the director of the leper hospital in Bergen.

Deaths of Physicians.—During 1911, 2,145 physicians have died in the United States and in Canada; this gives an annual death rate of about 15.32 per 1,000.

Obituary Notes.—Dr. NORTON R. HOTCHKISS of New Haven, Conn., a graduate of the University of Maryland School of Medicine, Baltimore, in 1891, died at his home, January 30, at the age of 41.

Dr. Norton Royce Hotchkiss of New Haven, Conn., a graduate of the University of Maryland School of Medicine, Baltimore, died at his home January 30. He was former Surgeon-General on the staff of Governor Woodruff, and president of the New Haven Medical Association. He was forty-two years old.

Dr. Isaac Poole of Evanston, Ill., a graduate of Berkshire Medical College, Pittsfield in 1862, died at his home January 24, at the age of seventy four years. During the Civil War he served as surgeon on the battleship *Kansas*.

Dr. Oscar Czarnowski of New Orleans, La., a graduate of the medical department of Tulane University of Louisiana in 1873, died of pneumonia at his home January 24, at the age of seventy-five years.

Dr. Charles W. Oliver of Washington, D. C., a graduate of the medical department of George Washington University, died at his home January 26, at the age of twenty-five years.

Correspondence.

BRILL'S DISEASE AND TYPHUS FEVER.

To the Editor of the Medical Record:

Sir:—Your editorial in the Medical Record, February 10, 1912, is hardly fair in attributing to me a refusal to admit the identity of the disease, described by me some time ago, with typhus fever. It is a well-known fact that I was the one who first pointed out its clinical resemblance to typhus fever and that I was also the first to conduct experiments by inoculating blood from a few of my patients, who suffered with the disease, into monkeys in the effort to establish the identity. The failure of these experiments to transmit the disease to monkeys, the marked differences in the epidemiological factors, the negligible fatality of barely 1 per cent. were factors that induced me to express the opinion, as anyone may see, by referring to my article in the *American Journal of the Medical Sciences*, August, 1911, that the identity with typhus was further than ever from being *indubitably* established.

Anderson and Goldberger succeeded where I failed, even though they encountered a similar failure with the first three of their monkeys in transmitting the infection. I need only refer to the facts that in my article just quoted, published considerably before their experiments were conducted, I begged other investigators to carry on this work further to prove the identity, and that I was the one to furnish Anderson and Goldberger with the material for that work and for which they give me credit in their report.

I had to fight for years with the profession to secure a recognition of this disease, which every clinician in the city who saw it insisted was a modified typhoid fever. Even on reporting a fatal case as typhus fever the Health Department refused to regard the disease as such, though one of the officials made the autopsy. It gave me the greatest satisfaction to have the disease taken from the typhoid category by the investigations of the committee appointed by the New York Academy of Medicine (Report of Committee to the Section on Practice, December, 1910) because that was a step forward in the direction of progress.

It is hardly just, therefore, to be placed by your article in the list of "doubting Thomases," especially when all the investigations to establish the identity of the disease described by me with typhus fever were instigated by myself.

N. E. Brill, M.D.

48 West Seventy-sixth Street, New York.

[The statement to which exception is taken by Dr. Brill was based upon a letter in the *Journal of the American Medical Association* of December 2, 1911, in which he said that until stronger evidence was produced he would be "justified in calling this disease an infectious disease of unknown origin."—Ed.]

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SURGICAL TREATMENT OF ASCITES DUE TO CIRRHOSIS OF LIVER—NEXT INTERNATIONAL MEDICAL CONGRESS—ANTI-TUBERCULOSIS CAMPAIGN IN WALES—OBITUARY.

London, January 26, 1912.

A long discussion on the operative treatment of ascites due to cirrhosis of the liver engaged the attention of the Surgical Section of the R. S. M. on the 9th inst. Mr. Morison opened it with a paper in which he described the procedure he had adopted and which he said was suggested to him by a visit to the post-mortem room, when Dr. David Drummond showed him a body in which cirrhosis had been fatal and there had been no ascites because the portal obstruction had been relieved by the collateral circulation—chiefly through enlarged Sappey's veins. Neither of these gentlemen were aware at the time that Professor Talma had performed an operation to establish a new anastomotic circulation in such a case, but they considered the possibility of doing so, and in the light of the enormous new vessels that are met with in rapidly growing abdominal tumors some such operation seemed feasible. In the first case in which they attempted this method of dealing with ascites the disease did not result from cirrhosis and the patient died nineteen months afterward, unrelieved. A second attempt was successful, and the patient was shown at the British Medical meeting at Carlisle eight months later in apparently good health. Other cases were mentioned, but it was emphasized that those in which the operation can be of use are rare and must be carefully selected. Mr. Morison said, so far as he knew, those of alcoholic origin in patients otherwise sound and whom repeated tapping failed to cure were most suitable, as none such had proved failures. Perhaps the reason is similar to the cure of dropsy due to heart strain, the chief predisposing cause being removable—the heart being relieved by rest, even by abstinence from alcohol. Mr. Morison detailed the technique he has employed, laid stress on strictest antisepsis and the after-treatment, and said reaccumulation sometimes took place after the operation and required tapping once or even twice, but need not cause anxiety.

Dr. Hale White began the discussion by expressing agreement with Mr. Morison that suitable cases were rare; he would say extremely rare. None of the successes were, he held, ordinary cases. Pressure on the portal vein was hardly the chief cause, for ascites might come on quite suddenly, and ligation of the vein did not set up ascites. The operation might prove fatal, and, considering the decrease in alcoholism, would probably die out. Dr. H. D. Rolleston thought the increased anastamosis

acted by enabling the liver to deal more easily with the blood passing through and thereby reducing the toxemia, which appeared to be the chief cause of ascites. He could not agree with Dr. White that tapping was not often needed more than once. Mr. Waring preferred omentopexy. Mr. Sampson Handley thought the drainage method lately adopted at the Middlesex Hospital might eventually become the established plan, but in any case he thought the surgical treatment of ascites had come to stay. He rather preferred Wynter's plan of femoral drainage. Dr. W. Essex Wynter said that the practical point was the overdistention of the peritoneum with nutrient fluid withdrawn from the circulation. Thus resulted toxemia and emaciation. A striking fact was that anuria was likely to occur after each tapping. For this autoseropathy was employed by some French authorities—withdrawing some ascitic fluid and injecting it hypodermically. A serious disappointment often was seen in the patient not giving up his alcoholism. Some persons had continued drinking after three or four years of freedom from ascites. This trouble had been mentioned already by Dr. Handley.

Mr. Spencer regarded the operation as to a certain extent exploratory, and there was a great advantage in exploring the abdomen in cases which had been repeatedly tapped. He recalled some in which diagnosis had been erroneous. He had varied the method in some cases. In one woman the Morison plan had done her much good and she wanted a repetition. He scraped the liver on the plan of Mr. Turner of St. George's Hospital, which relieved for a time. At a third operation he put a glass button in (Paterson's method). He had seen no injury from these operations, and felt sure they prolonged life. Dr. Parkes Weber had had four of his cases operated on by Mr. Michels, all successful. He thought cases which developed easily collateral circulation did not often have ascites, but others whose circulation did not thus develop had ascites early.

Dr. S. White of Sheffield sent a statement of nineteen cases, which was read for him. Five were fatal from different causes. Of the other fourteen three died within a year and two had to be tapped before the cure was complete. Mr. Makins said he had operated in five cases, four of which had been previously tapped several times.

It seems rather early to be talking about the next International Medical Congress, but those concerned with the arrangements think it is none too soon. The meeting is to be in London, and August 6, 1913, is fixed for the opening day. It will be thirty-two years since the meeting took place here. On that occasion Lister was present and antiseptic surgery the subject of discussion and even disputation to every little coterie of members and visitors. Sir J. Paget presided with the calm and courtesy which always distinguished him; Pasteur, Virchow, Huxley, Gull, and others whose memory remains were among the prominent personalities. For next year the King has promised his patronage, and Prince Arthur of Connaught has agreed to open the Congress. Ehrlich is to give the address on Pathology, Chauffard that on Medicine, and Harvey Cushing that on Surgery. There are to be twenty-two sections and subsections. You see, we are getting on—and there is need for activity, for it is estimated that £12,000 or £13,000 will be necessary to ensure success.

A royal charter is about to be issued to the Welsh Memorial Fund for King Edward VII., which takes the form of an anti tuberculosis association for the Principality and Monmouthshire. The association is representative of all classes, as well as of local authorities, especially those connected with health and sanitation. Nearly £200,000 has been contributed, and the Welsh Insurance Commissioners are to have power to make grants toward some of the proposed work. This will be to a large extent educational, an active effort being made to spread a knowledge of the risks involved and the method of prevention. But treatment, sanatorium and other, will receive attention, and arrangements for this will probably be made in conjunction with county councils and for insured persons with the local insurance committees.

Yesterday the announcement that Sir Henry Butlin died on the previous day came as a shock to many of his admirers. Even those who remembered he had been obliged by ill health to retire from the presidency of the Royal College of Surgeons thought perhaps the breakdown was due to overstrain, for he held in the same year the presidency of the British Medical Association. It seems such a little while since he delivered his two Hunterian lectures on cancer and proposed the name of *Unicellula cancri* for the cell. I gave you some account of these lectures in my letter of December 1, and you commented on his theory in your leader of December 16. That he was a general favorite in the profession was shown last June when we entertained him at a complimentary banquet. That was the occasion on which he spoke of the crisis threatened by the Insurance Bill and declared that we had as much right as any class to enforce our claims by a united refusal to work for inadequate remuneration, thus showing that although not dependent on the profession he had full sympathy with those less fortunately placed and whose living he considered the scheme endangered. He was soon after this banquet created a baronet, an honor it was generally held he well deserved for his surgical work. In 1868 he was house surgeon at St. Bartholomew's Hospital, with which he has continued to be connected throughout his life, being surgical registrar in 1872, later demonstrator of surgery, and taking the next vacancy on the assistant staff. In 1892 he became full surgeon, and on resigning after ten years was made consulting surgeon. He was attached for some time to the Hospital for Sick Children. He was dean of the faculty of medicine in the London University.

Dr. Cecil Yates Biss, late physician to the Brompton Consumption Hospital, died on the 20th inst., aged 66. He was a Cambridge graduate in arts and medicine, taking honors in the several stages; M.D., 1884. He was elected F.R.C.P. in 1889. He had been also connected with the Middlesex Hospital, in the school of which he lectured on pharmacology and therapeutics. He had also been an examiner in materia medica for the College of Physicians and the Apothecaries' Society.

Dr. C. A. Lee of Hull died on the 13th inst., aged 86. He went to Hull in the year he graduated, 1848, and had practised there up to a short time ago. He was deeply interested in the infirmary and other public institutions of the place, which he served in various ways. Shortly before his death he conveyed a site to trustees for the purpose of erecting almshouses, and he has left by will a large sum of money to carry out his intention.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

GENERAL HEALTH CONDITIONS—MANILA WATER SUPPLY—INCREASE IN BERIBERI—CHANGE IN PUBLIC ATTITUDE TOWARD HOSPITALS—THE CHOLERA CARRIER—PERSONAL.

MANILA, December 9, 1911.

THE close of the year 1911 finds the Philippines in better condition from a health standpoint than they have probably been at any time during the past 200 years. There is no plague among men or rodents; no cholera has been reported for nearly six months; smallpox exists only in sporadic form. The installation of the new water system in the city of Manila has reduced the incidence of the intestinal diseases by almost one half. There are, however, a great many cases of so-called varioloid through the Islands. There is considerable dispute among the local physicians as to whether it is really varioloid or varicella. Be that as it may, there is no mortality from the disease, and the person afflicted with it are usually so mildly ill that they resent being called sick.

The new water system for the city of Manila has now been in operation since November, 1909, and sufficient time has elapsed to make it practicable to compare the number of deaths from intestinal diseases with the number which occurred prior to the time the new water became available. It will perhaps be remembered that previously the water for the city of Manila was obtained from a watershed upon which at least ten thousand persons lived, and who considered it their unalienable right to polute and defile the stream as they wished. The water now comes from a practically uninhabited watershed, some thirty miles distant from Manila. Up to the present time no filtration system has been installed, and the water is the ordinary surface water that is found in the tropics and contains amebiæ, with a bacteriological count that varies approximately from 150 to 300 per cubic centimeter. It is the intention ultimately to provide a purifying or filtration system, but this has not been undertaken up to the present time owing to the fact that there is not yet sufficient evidence available as to whether the amebiæ found are pathogenic or nonpathogenic. The experimental sand filters which have been tried have all permitted the passage of amebæ, so that if it should prove that the amebæ are pathogenic some other system of purification would have to be used. In spite of the lack of filtration it is interesting to note the decrease which has taken place in many of the so-called water-borne diseases. For instance, for the fiscal year ended June 30, 1907, there were 586 deaths from cholera, whereas for the fiscal year ended June 30, 1910, there were 146 deaths from this disease. For 1907 there were 344 deaths from dysentery, and in 1911, 143. Of convulsions of children which are generally admitted to be due to intestinal disturbances, there were, in 1907, 1,315 deaths, and in 1911, 510. Of chronic diarrhea and enteritis, under two years of age, there were 224 deaths in 1907, and 120 in 1911. Among persons over two years of age there were 353 deaths from diarrhea and enteritis in 1907, and 151 in 1911. From the foregoing it will be seen that there has been a reduction of almost one-half in these water-borne diseases.

In this connection, however, it is interesting to note that there has been an increase in the beriberi deaths. In 1907 there were reported 407 deaths from beriberi, whereas in 1911 there were 1,515 deaths from this disease. Allowing a reasonable percentage for errors in diagnosis, and making allowance for the fact that there was probably more attention given to beriberi on account of the large amount of discussion which has taken place within the past two years upon the etiology of this disease, there would still remain a large number of deaths which require an explanation. The Filipino, as well as the Chinaman, the Malay, and the people of Japan, is very fond of highly polished rice. In view of the gradual increase which has taken place in the wages of the Filipino laborer, it has been possible for him to purchase more rice, as well as a more costly quality than formerly, and it is believed not to be unreasonable to infer that the increase in beriberi is directly due to the increased consumption of polished rice in the Philippine Islands. It may, perhaps, be further explained on the basis that a large bulk of the rice grown in the Philippine Islands is not highly polished before it is used. During the past few years, owing to failure of crops here, it has been necessary to import large quantities of rice from Indo-China and other countries where it is customary to machine polish it before shipment. It is evident, then, that there has been very much more polished rice used during the past few years than was formerly the case, and that this may well account for the increase in the number of deaths from this disease.

Since the opening of the Philippine General Hospital in September, 1910, there has been a great change in the public attitude toward hospitals. Before that time the Filipino looked upon a hospital as a place to go to die, and the fear of a hospital was almost universal among the masses. At the beginning it was most difficult to induce the average Filipino to enter a hospital, but by patient insistence, and with the evidence of the actual benefit before his eyes, the conversion is going rapidly on. That this attitude has changed completely is probably best evidenced by the number of persons who are at present treated in the hospitals in the city. For instance, at the Philippine General Hospital, persons are now applying for treatment at the out patient department at the rate of 80,000 cases per year, thus making it one of the largest out-patient dispensaries in the world. Other hospitals in the city which have opened within recent years report similar increases in the number of applications for relief. The Philippine General Hospital has 350 beds, all of which are constantly filled, and applicants for admission must be turned away daily. Medical men here are now beginning to fear that the time will soon come when there will be implanted into the Philippines the same abuses of hospital privileges which have caused so much trouble in Europe and America.

That the cholera carrier is probably one of the most important factors to be considered in successfully dealing with this disease was again well illustrated by an incident which occurred in the city of Manila. During the month of July a person was seized with the disease. There were seven contacts in the same house who, upon bacteriological examination, all proved to be harboring the cholera vibrio, but who were not in any way ill. These cases were isolated and treated with calomel, and within a period of ten days none of their dejections was cholera-infected. Last week a curious incident occurred in connection with these same cases.

One of their number was taken violently ill with the clinical symptoms of cholera, but these cleared up in the course of ten hours, and the bacteriological examination of the stools did not reveal any cholera organisms. An examination was again made of the stools of the contacts, and no cholera vibrio was found.

Captain Philip W. Huntington, United States Army Medical Corps, who has been on duty as sanitary officer with the Bureau of Navigation of the Philippine Government, has been ordered to the United States, and will be succeeded by Captain Robert L. Caswell, United States Army Medical Corps.

Diagnosis of Diseases of the Stomach and Intestines by the X-Ray. E. A. Codman.
Past and Present Methods in the Practice of Medicine. O. Worcester.
Blood Pressure in the Toxemias of Pregnancy. (Second Communication.) R. M. Green.
Infiltration Anesthesia in the Submucous Resection of the Nasal Septum. I. Sobotzky.
Cases from the Skin Department of the Massachusetts General Hospital. Service of John T. Bowen, M.D. J. H. Blaisdell.
A Case of Myiasis. H. B. Hart.

X-Ray Diagnosis of Diseases of the Stomach and Intestines.—E. A. Codman states that by means of one examination, the details of which he describes, the radiologist can give an opinion on the following points: (1) whether or not there is abnormality in the size, shape, contour, position, tonicity, and motility of the stomach; (2) whether or not there is residue after six hours; (3) whether or not there is delay in the passage of the food through the small intestine and ileocecal valve.

Methods in the Practice of Medicine.—A. Worcester contrasts the family practice of former days with the specializing tendencies of modern times.

Blood Pressure in the Toxemias of Pregnancy.—R. M. Green states that in a former paper he classified these toxemias as follows:

TYPE.	BLOOD PRESSURE.	
A. Eclampsia:	*Before Delivery.*	*After Delivery.*
1. Impending.	Moderate.	Failing.
2. Acute.	High.	Falling.
3. Fulminating.	Extreme.	Rising.
4. Postpartum.	?	Moderate; falling.
B. Chronic nephritis.	Moderate.	Rising or constant.
C. Hyperemesis.	Moderate.	Constant.

To these groups he now adds the two following: (1) postpartum eclampsia, which is a condition of cumulative toxemia in which the resistance of the patient's central nervous system prevents the outbreak of symptoms until after labor; (2) cases of pernicious vomiting, with fairly normal blood pressure, in which the condition progresses to a fatal result, with a rising ammonia coefficient, unless the uterus is emptied.

Infiltration Anesthesia in the Submucous Resection of the Nasal Septum.—I. Sobotzky notes that it has been found that anesthesia can be produced by the subperichondrial injection of a normal salt solution to which a few drops of adrenalin have been added. This solution can be used without fear of the distressing absorption symptoms that accompany the use of cocaine. The technique is simple. A weak cocaine solution, either of 2 or 4 per cent., is applied to the mucous membrane on either side of the septum. This is done to render painless the introduction of the needle of the syringe through the membrane to the cartilage. The anesthetic and hemostatic consists of 10 c.cm. of a sterile normal salt solution to which are added 4 minims of a 1:1000 adrenalin solution.

Cases of Rare Skin Disease.—J. H. Blaisdell reports a case of papulonecrotic tuberculides and one of generalized unpigmented nevi.

A Case of Myiasis.—H. B. Hart reports a case of intestinal infection of a woman with the maggots of one of the smaller and less common house flies, the *Anthomyia canicularis*.

The Responsibility of the Medical Profession for the Early Diagnosis and Prompt Treatment of Pulmonary Tuberculosis. E. O. Otis.
An Explanation of the Positive Wassermann Test Following Some Cases of Anesthesia. S. L. Cherry.

Relief of Prostatic Obstruction.—By J. Bentley Squier. (See MEDICAL RECORD, January 20, 1912, page 144.)

Amputation of Penis.—G. F. Lydston and H. F. Steere report a case of complete amputation of the penis by a jealous wife. They state that the psychology of cases of genital injury by criminal assault varies: The causes are as follows. (1) Simple jealousy. Women sometimes injure not only the offending male, but also the female rival, making the genitals the object of assault. The male often makes the genital organs the objective point of assault upon a rival. The dominant idea is in most cases simply revenge. (2) The desire to deprive a rival of what seems to the jealous person the chief point of interest to the rival. (3) A desire to punish the one at whose hands the assailant has suffered injury. (4) Both women and men have been known to commit sex mutilation on persons in whom they no longer had an interest. (5) The desire to protect oneself from future encroachments on one's sexual rights. (6) Insane impulse. (7) Reversionary instinct, resulting in sadism. Apropos of this point the attack of the female spider and of the female *Mantis religiosa* upon the male after copulation are illustrations.

Diseases of Posterior Urethra.—J. H. Hawkins, in reviewing his methods of treating these conditions states that the day of treatment of diseases of the posterior urethra by sounds and instillation alone is long past, and with the etiology and pathology fairly understood the use of more rational methods should give more satisfactory results.

Keratitis Rosacea.—B. Chance reports a case of this condition.

Tuberculosis.—A. Rose refers to this disease under the name "phymatiasis," which he believes should be treated in "therapeutaria" or "iatreia" rather than in sanatoria. Abdominal strapping is recommended for the gastric atony associated with these cases, while the method of rectal injection with carbon dioxide is again brought forward as a therapeutic aid. The continuous warm bath is believed by the author to be the most rational remedy in tuberculosis, that is to say, in phymatiasis.

Alcohol and the Individual.—H. Brooks describes the pathological effects of alcoholic indulgence.

Alcohol and the Stomach and Liver.—M. M. York refers to the injurious effects of alcohol upon the gastric and hepatic functions.

Serum Treatment of Hemorrhage.—H. W. Lescohier states that in the causation of hemophilia the quantity of zymoplastic substances is of little importance, as these have been shown to be present in hemophilics to a degree equal to that in the normal individual. Rapidity and completeness of coagulation is directly proportional to the amount

of thrombin present. There is a direct proportion between the quantity of thrombin present and the amount of fibrin produced. Clinical experience shows that relatively large amounts of serum must be employed to produce definite results.

Early Diagnosis and Treatment of Pulmonary Tuberculosis.—E. O. Otis states that the control of this disease depends upon the universal dissemination of knowledge regarding tuberculosis in general, and regarding the results obtained when the disease is treated early, at the right time, when arrest is probable; or late, at the wrong time, when death is probable; the establishment of free dispensaries; examination of workshop and factory operatives; better medical inspection of schools; some form of automatic provision for families of tuberculous individuals while they are under treatment; perhaps a workman's compensation law against sickness; more assurance of employment when cured; special instruction and training in medical schools in early diagnosis; and, finally, the deeper and fundamental remedy—prevention of all those causes which lower normal resistance: poverty from a nonliving wage; bad housing; insanitary and dusty workshops; alcohol; and all the other preventable causes.

Wassermann Reaction Following Anesthesia.—S. L. Cherry states that anticomplementary bodies are formed in the blood of dogs during chloroform anesthesia, and these cannot be removed entirely from the serum by heating it to 55° C. for thirty minutes. (2) It is evident that when antigen, possessing anticomplementary properties in undue amount, is combined with a serum possessing anticomplementary properties, the total of the two may be sufficient to cause more or less fixation of complement in the Wassermann test. The purer the antigen is, therefore, the more strongly a positive Wassermann test points to syphilis. (3) No antigen, however made, is permanent, and the main thing is to use an antigen as strongly antigenic and as weakly anticomplementary as possible.

Journal of the American Medical Association.

February 3, 1912.

Treatment of Acute Endocarditis and Myocarditis.—F. S. Meara states that in these conditions the heart should be relieved by the avoidance of any strained or uncomfortable position, mental work of worry, and especially by sufficient refreshing sleep. Moderate doses of bromide may be found sufficient, but if not, other drugs should be called in, and the author prefers among the various hypnotics chloralamide or trional, but if these do not suffice, chloral or morphine may be required. The former is reliable, but its depressant effects must be considered, and he would give it only in the excited sthenic heart of rheumatic endocarditis; in the myocardial involvement, especially of pneumonia and diphtheria, he would not employ it. Morphine is reliable and safer. The medicinal treatment should be directed mainly to the cause of the heart involvement and here the salicylates are depended on, combined with alkalies. The local measures, cold, heat and local irritation, can be used and will suffice in most first attacks of rheumatic endocarditis. In later attacks cardiac tonics may be required to meet cardiac insufficiency and digitalis is the most reliable of these.

Drug Addiction and Mental and Nervous Diseases.—C. C. Wholey states that alcoholism may induce neuritis ranging from slight paresthesias to more serious conditions. It may cause optic atrophy and other morbid conditions of the cranial nerves and direct cortical involvement with or without peripheral alteration, as is shown in alcoholic types of insanity. The addiction to morphine, alcohol and other drugs may also appear as an effect as well as a cause of neuroses, and it may be a symptom of an involutionary process, as is sometimes seen in the aged who have long been temperate. It may occur in ordinary manic-depressive insanity and in paresis, of which it is often a contributing cause. There are many conditions in which the addiction may figure both as cause and as effect. Alcoholism in the ascendents may establish disease or susceptibility of the nervous system in the offspring, which may in turn be the chief factor in the etiology of intemperance. The effect of alcohol and other narcotics in masking or obscuring the clinical pictures of other serious disorders is well known.

Chronic Otitis.—W. A. Wells notes that there is a large percentage of cases which may be successfully handled if the proper methods of non-surgical treatment are employed. The object is not primarily the cessation of the discharge, which is merely a symptom, but the pathological process on which it depends. The treatment should be directed in some cases to the general health, in many cases to the state of the nose, nasopharynx and Eustachian tube, and in all cases to the middle-ear and its immediate adnexa. In some cases tonics, hygiene and exercise are to be directed and if tuberculosis or lues are present they must be treated. In children a chronic suppuration of the ear, not following measles, diphtheria or scarlatina, is almost certainly dependent on adenoids. The local treatment should be directed to the removal of the purulent secretion or other disease products, the sterilization of the parts and the prevention of sepsis and the use of selected medicinal agents to assist nature to normal condition. Disinfection of the nasopharynx and washing out of the ear, as well as suction by the Fowler apparatus which combines it with irrigation, are mentioned. It is only by the instillation method, properly done, that the medicine can be made to reach the desired place in a sufficiently concentrated state. The best agent for this method is alcohol, either alone or carrying with it such other drugs as boric acid, iodine, silver nitrate, etc. The alcoholic instillations may be used every day, or even oftener, according to the individual case.

Cocainism.—W. D. Owens describes the symptoms of this condition.

Rhythm in Apoplexy.—J. H. Hurst reports a series of five consecutive cases of apoplexy in which there was a periodicity in the recurrence of the attacks. The danger periods appeared not to exceed five days and to recur at approximately thirty-day intervals. Prophylactic treatment during these danger periods alone has lessened very materially both the frequency and severity of the attacks. During these danger periods the blood-pressure was much in excess of that for the remainder of the month. The ultimate cause appears obscure. It is suggested that the phenomenon may be due to (1) influences originating in the nervous system; (2) the products of germ or parasitic activity; (3) mechanical compensatory changes of blood-pressure; (4) disturbance of metabolism, assimilative or eliminative, or (5) to the function, or disturbance of function, of a gland or chain of glands possessing an internal secretion.

Hexamethylenamine in Treatment of Bronchitis.—D. Vanderhoof recommends the use of this remedy in the treatment of acute colds and in acute and chronic bronchitis.

Acanthoma Adenoides and Syringocystadenoma.—R. L. Sutton and C. C. Dennie state that lymphangioma tuberosum multiplex or, better, syringocystadenoma, is a non-malignant, cystic neoplasm derived from misplaced embryonal coil-gland elements. The cells still retain their sweat-secreting function, hence the tumors are true adenomata. Although these growths are, in reality, benign cystic epitheliomata, they distinctly differ, both clinically and microscopically, from the acanthoma adenoides cysticum originally described by Brooke and by Fordyce. If the term "multiple benign cystic epithelioma" is to be retained, its use should be confined strictly to tumors of the Brooke-Fordyce group, and a more fitting and proper designation, as syringocystadenoma, adopted for the neoplasms which have so long been indexed under the euphonious but misleading appellation of "lymphangioma tuberosum multiplex."

Nonunion of Fractures.—J. S. Horsley states that the non-union of fractures is the failure of the tissues to deposit lime salts, and after excluding all local and constitutional causes there still remains a group of cases in which this condition seems to occur and the bones fail to unite. There are two indications for the treatment of these cases, namely, to increase the quantity of lime salts in the blood and, second, to induce a larger quantity of blood-flow through the affected bone.

Hospital Decoration.—H. A. Gardner states that cold water paints are insanitary as well as non-durable. They cannot be washed down. Some paste-paints, recently introduced, containing a rosin binder mixed with glue, dextrin and other water soluble materials are even more objectionable than ordinary calcimine. The older method of washing the oil from white lead with turpentine and applying it as a flat paint should no longer be practised, as it is liable to produce a toxic lead dust. In order that a paint may be suitable for hospital walls it should, on drying, leave a hard, elastic, impervious surface which can be washed with water or antiseptic solutions or subjected to the fumes of formaldehyde and sulphur dioxide. The pigments must be permanent and unaffected by the caustic lime that may exist in cement or plastered walls. In public and private wards, where the patients' eyes must find restful surroundings, the modern sanitary flat wall finishes are preferable on account of the non-reflective surfaces they present. For operating rooms and the general trim of a hospital, satin or gloss finish enamels are best. They are sanitary and very durable. The painter should allow each coat to dry firm and hard before the next one is applied. With the introduction of cement for hospital floors a new problem arises. The surface wearing of these floors and the consequent dusting calls for properly designed cement coatings. These should be made largely of hard, abrasion-resisting pigments ground in an oil that will not saponify when in contact with the alkali-bearing cement and still be of such a nature as to produce a hard, glossy surface that can be flushed with water or dilute antiseptic solutions at any time.

Prostatometer.—H. J. Scherck describes an instrument for measuring the size of enlarged prostates. It is based on the caliper principle, with a rectal and a vesical arm, the former being properly curved and the latter consisting of a flexible metal sound for about two-thirds of its length.

Magnified Heart Sounds in Extracardiac Conditions.—O. H. P. Pepper reports an unusual case of magnified heart sounds due to extracardiac conditions occurring in a boy, aged 14, who had a greatly hypertrophied heart from endocarditis with badly damaged mitral and aortic valves. From the description Pepper had received before seeing him he had carefully considered a hydropneumothorax or hydropneumopericardium, but there was no evidence of either on examination. The sound could be heard from a point ten feet away, and was synchronous with a pulsation seen in the neck. It was a mixture of a tympanic note with a slight splashing element. It could be best reproduced by percussing very forcibly a dilated stomach half full of fluid, and this was just what the heart was doing.

Menstrual Suppression in Hypothyroidism.—C. Macfarlane reports a case illustrating this association.

Infectious Hemoglobinuria.—W. G. Little describes a case of this condition which is commonly known as Winckel's disease.

The Lancet.

A Note on Glaucoma. L. Hill.
A Case of Rhonnus Cavosus. H. W. Wilson.

Mental Processes in Sanity and Insanity.—T. Claye Shaw states that the insane person is really sane in his type, he is saying or doing the only thing possible to his existing conditions. The paradox that "there is no such thing as insanity" connotes that an insane act or delusion is the necessary result and the only one possible in a given state. The clue, then, to what is going on in the mind of an insane person is to be found by following up his speech and actions until one arrives at the ultimate state which alone could cause them, for there the trouble lies, and not in the manifestations which set up so much alarm, but which are really nothing but danger-signals—and this eventually comes to an inquiry into motives.

Ether and Open Ether Methods.—Sir F. Hewitt and W. Legge Symes conclude that the percentage of ether afforded by a Skinner's mask properly adjusted, lies ordinarily between 5 and 15 according to the extent of douching and the nature of the fabric employed. Gauze yields a higher percentage than lint or flannel, the percentage rising roughly according to the number of layers. With flannel or with lint, so adjusted that all inspirations and expirations pass through the fabric, a more or less equable atmosphere containing approximately 8 or 9 per cent. of ether vapor may be depended upon.

Alcohol Injection of the Gasserian Ganglion.—W. Harris states that the great advantage of extirpation of the Gasserian ganglion over Schlösser's method of alcohol injection of the nerve trunks has been the permanence of the cure in the former treatment, as opposed to the temporary relief of a few months to three or more years obtainable by the injection. It appears possible to obtain all the advantages of the Krause-Hartley operation without its attendant deformity and dangers, or even the necessity of a general anesthetic. In practically every case it is possible to pass the needle through the foramen ovale into the Gasserian ganglion. The technique for injecting the Gasserian ganglion varies only in detail from that of injecting the inferior maxillary nerve at the foramen ovale: instead of inserting the needle close below the lower border of the zygoma, a point is chosen either on or slightly below the line joining the incisura notch to the ala nasi. This line in the average skull, when the teeth are in position, corresponds to the lower border of the sigmoid notch of the lower jaw. To reach the foramen ovale, therefore, the needle must be directed slightly upwards, making it thus easier to pass the point through the foramen. As soon

as the nerve is reached at the foramen. The canal is rinsed out with 60 per cent. alcohol, using about 1 c.c., but if no general anesthetic is being given he precedes the injection of the alcohol by injecting 6 or 7 minims of 2 per cent. cocaine solution into the nerve, thus rendering the subsequent injection of the alcohol comparatively painless.

Surgical Treatment of Sterility in Women.—T. J. McCann notes the important rôle of gonorrhœa in the causation of sterility in both sexes. In the female the results produced in the tubes and ovaries through gonorrheal infection often lead to permanent sterility. Infection post-abortum and postpartum or infection the result of appendicitis may lead to a similar result, while tuberculosis may also be a cause. Such infections produce adhesions of the ovaries and tubes to the back and side wall of the pelvis, to the rectum, to the uterus, or to one another, or the Fallopian tubes become thickened and their abdominal ends closed. Improvement under appropriate treatment may result, but with gonococcal infection the results tend to persist, the outstanding features of this infection when attacking the Fallopian tubes and pelvic peritoneum being its chronicity and its tendency to form adhesions. The operation of making a new abdominal opening for the Fallopian tube is termed salpingostomy, and was first attempted by Skutsch in 1880. Uterine displacements account for certain cases of sterility. Curetting in the treatment of sterility is indicated in cases of what is termed chronic glandular hypertrophic endometritis associated with free menstrual loss occurring in a uterus normally placed and where no tubal disease exists. Sir J. Y. Simpson devised the operation of bilateral division of the cervix for the cure of sterility, and undoubtedly he was successful in many cases. If this operation be considered in the light of modern experience it fulfils many indications. It causes wide dilatation, it cures dysmenorrhœa even when simple dilatation fails, it provides free drainage, and so may lead to improvement in the condition of the endometrium.

The Klebs-Löffler Bacillus.—L. C. Fogely notes that this organism has been found in leg ulcers, nasal discharges, discharges from the eye, and in the urethral meatus.

Ulcerating Granuloma of the Pudenda.—J. Steel states that in the lesions of this disease spirilla of various kinds are found, some resembling the *Spirillum refringens*, some the *Treponema pallidum*. Another parasite was sometimes in evidence, usually in the fungating, granulomatous variety of the infection, and often from the enlarged inguinal glands, when such are present. Generally seen in the large, swollen mononuclear cells, and often in considerable numbers, they possess varying appearances; if for any reason they appear crowded together the bodies resemble enlarged cocci or bacilli, sometimes kidney-shaped, not unlike huge gonococci. The author believes that this condition consists of two distinct diseases, or an infection of an already diseased subject with another germ. The latter organism is presumably the agent described by Manson as occurring in India.

Glaucoma.—L. Hill believes that the cause of the increased tension in glaucoma primarily is altered metabolism. This is produced by bacterial toxins or otherwise, and results in chemical changes in the colloids of the eye which swell by absorbing more water. Obstruction of the venous and aqueous outflow by sclerotic changes with resulting lack of oxygen and increased production of acid may well be a possible cause.

Rhinitis Caseosa.—H. W. Wilson reports a case of this condition occurring in a girl aged eleven years, and manifesting itself in a yellowish discharge from the nose and the presence of a yellowish-white membrane on the outer wall of the nasal fossa. The material removed had a slight fetor and appeared more like putty than anything else. It was greyish-red in colour, of a soft, friable consistency, but at the same time was different from the ordinary caseous material one associates with tuberculous disease. Microscopically, the bulk of the mass was seen to consist of large numbers of long fine needles, mixed with a structureless material, the former probably of a fatty nature. In addition there were numerous micro-organisms, a few pus cells, and a few small crystals. No mycelial threads could be found. The cultures taken showed a short-chained streptococcus and *Staphylococcus pyogenes aureus*.

January 27, 1912.

Resistance to Disease.—A. R. F. Exham states that one of the local defences is the process of inflammation. Sir Watson Cheyne has some doubt whether the leucocytosis that accompanies the early stage of inflammation is quite as important as most men believe, holding rather that the essential resisting power of a part to local infection lies in the tissue cells rather than in the adventitious leucocytes which come into it subsequently. At any rate, leucocytosis is one factor in defense. Fever is in some way related to defense, and its absence where it might be expected is very often of the gravest significance. Again, there is the general question of the resisting power at various ages. Children seem to be less immune but more resistant to any acute infectious conditions. The exanthemata are far more frequent in children, and yet, as a rule, they are apt to be more severe in adults. Pneumonia, again, is more common in young people; in them the mortality is very low, but rises steadily in proportion to age. On the other hand, typhus is not so common in children, yet it is said to be not so dangerous in them. Typhoid fever is not as frequent in young children as in young adults, and is more frequent in the latter than in older persons, yet the mortality is smaller in young children and rises progressively as age advances.

Diagnosis of Spinal Cord Affections.—D. Forsyth states that these conditions may be arranged in three groups. (1) Those in which the symptoms come on all at once; (2) those in which the symptoms are acute, taking several hours or even days to develop; (3) those in which the symptoms are insidious. When the symptoms begin all at once there are only two lesions to think of—trauma and hemorrhage. In the former there is a history of injury, usually fracture-dislocation. In the latter, apart from injury, the cord has already been softened by myelitis or a new growth. Another possible cause of hemorrhage is pernicious anemia. Without warning, the patient becomes paralyzed and anesthetic up to the level of the injury. When the symptoms come on acutely one should think of (1) an acute infective process in the cord; (2) some thrombosis in the spinal vessels, and (3) acute spinal meningitis. Landry's paralysis and caisson disease belong to this group. Of the acute infective processes myelitis and poliomyelitis are examples. Spinal thrombosis is the result, apart from pathological states of the blood itself, of arterial degeneration, which, narrowing the vessels, hinders the streams of blood until it clots. This causes softening of the portion of cord supplied by

the affected blood-vessels. Syphilis is the cause of this condition. Senile endarteritis is another cause. The symptoms are not unlike those of acute myelitis. Syphilitic meningomyelitis begins with symptoms of spinal nerve root irritation, shooting and girdle pains, hyperesthesia and perhaps muscular spasm, followed later by paralysis and anesthesia; but still pain. The only truly spinal forms of meningitis are the syphilitic and the acute septic meningitis. The conditions in which the symptoms come on insidiously may be divided into two groups: those with motor symptoms only—progressive muscular atrophy, amyotrophic lateral sclerosis, primary spastic paraplegia, Friedreich's ataxia, and ataxic paraplegia; and those with both sensory and motor symptoms—tabes, syringomyelia, disseminated sclerosis, and compression of the cord. In progressive muscular atrophy the muscles of the patient's face and perhaps his deltoid and scapular muscles are wasted and show fibrillary contractions. In amyotrophic lateral sclerosis the patient's hand muscles are also the first to go, but the wrist jerk and triceps jerk are exaggerated. Later, the legs are affected and the process extends to the bulb. In primary spastic paraplegia there is absence of incoordination. The legs show the signs of lateral sclerosis. In Friedreich's ataxia the patient, usually a child, is unable to coordinate his legs, and later his arms and head, and his knee jerks are absent. His speech is peculiarly hesitating and he may have nystagmus. In ataxic paraplegia incoordination is present, but neither nystagmus nor affection of speech is present. The symptoms of tabes are well known. Syringomyelia, fully developed, combines the symptoms of progressive muscular atrophy in the arms with spastic paraplegia in the legs, and the patients are insensitive to pain and to heat and cold. In disseminated sclerosis the three cardinal symptoms are tremor, nystagmus, and staccato speech. Compression of the cord produces two-fold symptoms—those of spinal root irritation followed by root paralyses, and those of a transverse lesion of the cord itself.

Extramedullary Tumor of the Cervical Cord.—J. M. Clarke reports a case of this condition successfully operated upon.

Regeneration of Nerves.—B. Kilvington finds that the condition found after the restoration of a divided nerve trunk is very variable. These varying conditions render any definite statement as to prognosis and treatment extremely difficult, if not impossible. When no operation after secondary nerve suture has not taken place the main cause (apart from local conditions at the suture area, such as sepsis) is lack of regenerating power in the nerve cell. When all factors have been taken into consideration and it is concluded that restoration of function after secondary nerve suture is unlikely, there is still another surgical procedure open. This is the suture of the recently divided central nerve fibers to the distal trunk of the degenerated nerve—that is, by nerve anastomosis to an adjacent healthy nerve.

Pneumococcal Meningitis.—H. Drummond reports three cases of this condition.

Transient Hemiplegia Following Parturition.—H. Gillies reports two cases of this condition, apparently caused by a spasmodic contraction of the cerebral arteries.

Tetanus Treated by Subdural Injections of Magnesium Sulphate.—O. Smithson reports two cases in which this treatment was employed. Although both patients died the author believes that magnesium sulphate used in this way is a particularly potent drug.

Heat Stroke.—A. S. St. John reports a severe case of this condition. The remarkable recovery in a few hours from what appeared to be imminent death, on two occasions, after the withdrawal of cerebrospinal fluid, seemed to point to the fact that the patient was suffering from what might be described as a "blistering of his cerebral cortex," caused by the excessive heat rays of the sun in meningocortical edema, and that the fluid was being excreted faster than it could drain away, and by removing the excess the pressure was relieved.

Poliomyelitis.—L. S. Tomys presents a report of seven cases of this disease occurring in South Staffordshire.

Nitrobenzol Poisoning.—C. W. Hogarth reports a case of poisoning by nitrobenzol, commonly called oil of mirbane.

January 22, 1912

Experimental Nephritis.—Weiss and Maschke state that the problem of nephritis is not essential tendency to chronicity. They consider that the interstitial, all other so-called inflammations representing parenchymatous degenerations. Thus parenchymatous nephritis must be interstitial nephritis plus parenchymatous degeneration. The authors have performed different sets of experiments intended to illuminate the nature of the nephropathies. The kidneys were extirpated from one rabbit, and after it had in consequence become uremic, its blood was transfused into a healthy rabbit. Thereupon there developed in the latter evidences of intense functional activity of the kidneys, as shown by the degree of hyperemia and amount of granulation in the renal cells. It was evident that the latter underwent a certain amount of degeneration from the formation of nephrolysins. The degeneration was attended by extravasation of blood. Again as a result of innumerable punctures with a capillary needle the kidneys could be made to undergo contraction. The cycles of intact renal tissue could be seen in the act of doing compensatory work. In this sort of kidney there was no notable degeneration of the parenchyma as a result of the overwork, such as was evident in the first series of experiments. In a third set of researches it was sought to determine whether or not the constant excretion by the kidneys of foreign albumin could set up nephritis. The results when egg albumin was absorbed from the peritoneum and then eliminated by the kidneys were negative throughout. The authors are still experimenting and expect to publish all their finds in detail.

Indications for Renal Decapsulation.—Lehman concludes that Edebohls' operation is built upon false premises, which are not confirmed in practice and that in consequence it should be rejected outright. This, however, refers only to the operative cure of chronic nephritis. In itself it is justifiable because under certain circumstances it can prolong the life of a nephritic, even although there is no essential curative element in it. Further, decapsulation has an indication in so-called nephralgias and nephrorrhagias of angioneurotic origin. It is an emergency life-saving procedure in extreme oliguria, especially in the uremia of acute nephritis. It also facilitates permanent recovery from the latter and perhaps may actually contribute to it in some cases. In the uremia of chronic nephritis the operation is only justifiable if an acute exacerbation has occurred, the kidneys being still able to function. In purulent nephritis decapsulation may sometimes be conjoined with nephrotomy to favor drainage.

Industrial Diseases and Injuries of the Eyes.—Schnaudigel divides these as follows: (a) results of overwork or work under unfavorable external conditions; (b) lesions which occur as part of a general condition; and (c) direct injuries. Under the first head come the results of work on eyes with refractive anomalies. If student life may be defined as an occupation, school children may be included here for study in childhood and youth serves to bring out latent myopia, while the excessive use of the eyes in near work before they have attained their full development doubtless acts as a cause of short sight. In

regard to the second division, the eyes suffer notably in some occupations as part of a general process. The chief toxic agencies from this point of view are coal gas, lead, carbon disulphide, methyl alcohol, arsenic, mercury, nitrobenzole, etc., which are directly poisonous to the optic nerve. The third class, direct injury to the eyes, is naturally much more in evidence. Familiar examples are glass blowers' cataract, ophthalmia electrica, caustic burns, the keratitis of oyster shuckers and of other occupations in which the eyes are directly exposed to flying particles which do not have the force to penetrate. Penetrating injuries occur in certain metal workers. Direct injuries of the eye are very largely preventable by wearing goggles and by other means, so that in many cases the victims contribute directly to their condition by inconceivable folly.

Münchener medizinische Wochenschrift.

January 16, 1912.

Tricorrhexis Nodosa.—Hübner and Walter describe a remarkable wholesale incidence of this affection among schoolgirls. In addition to the manifest brittleness of the hair, the latter presented even to the naked eye the characteristic nodosities. The microscope showed the presence of the longitudinal fission. No sort of parasite could be found. While tricorrhexis nodosa is usually a sporadic affection, its endemic incidence has been noted from time to time in various localities. It has sometimes been assumed that for the production of this peculiar condition a gas-forming bacillus should be necessary, but no organism has ever been found constantly present, and hence it has been claimed that various bacteria can produce a common result, while from quite another point of view it has been demonstrated that the lesions may be set up by ordinary mechanical irritation. A study of the author's material appears to show, perhaps for the first time, that a predisposition is necessary for the development of this affection under ordinary circumstances. This was evident because the nutrition of the nails and teeth showed manifest defects. In the same subject there would be in evidence thin and lusterless hair, nails thin and flat, often excavated, and teeth which in the most pronounced cases were of the so-called Hutchinson type once believed to be pathognomonic of hereditary spyhilis. Since no boys were involved it was inferred that the exciting causes were mechanical and due to want of care and cleanliness. The subjects were children of people in the poorest circumstances, so that defective nourishment may be taken for granted. The fact that the condition improved in the summer months is explained by the greater energy of the hair growth during this season.

Groupwise Incidence of Heart Disease in Children.—Forell first refers to a description of this phenomenon by Max Herz, who recently narrated a so-called epidemic of acute endocarditis in Vienna, the victims ranging from six to eighteen years of age. A Hungarian practitioner also reported sixty cases of the same affection in girls in 100 such patients treated by him. The present author, then unacquainted with these reports, noted the occurrence of a petty epidemic in a restricted area, which, at first obscure, was found to be an infection characterized by a heart localization, which, however, was not the endocardium but the myocardium. There was no history or evidence of any earlier cardiac lesion. In Herz's cases not only was the lesion an acute endocarditis but there were evidences that the heart had previously sustained an injury. Again the present author has seen but seven cases, which is a very small number compared with the experience of the other practitioners. Hence Forell's cases may be regarded as in a class by themselves. Latent diphtheria was excluded, nor was there any evidence of a cryptogenous sepsis. In all probability the condition belonged under acute rheumatism. One patient at least out of the number showed an overwhelming predominance of rheumatic infection, hence the others may be regarded as of the same nature.

Treatment of Prostatic Hypertrophy by Stretching.—According to Kraemer, Freyel has proved conclusively that the severe cases of this affection are curable by extirpation of the growth. But since the operative mortality is so considerable as many cases as possible should be treated in a more conservative fashion. He would revert to the old-time resource of stretching the prostratic urethra. Recently he has cured six patients in this manner out of twelve so treated. The treatment entails little more intervention than ordinary catheterization and the use of the retention catheter. The instruments recommended are the urethral dilators of Bayer or Kollmann.

The Cammidge Reaction and Fusing Point Determination Under the Microscope.—Weber describes the Cammidge crystals which led their discoverer to the belief that he had found a certain urinary token of pancreatitis. Others who followed him could not corroborate his claims; but it is significant that the operating surgeons are the most enthusiastic vouchers for the practical character of the test. In at least 70 per cent. of cases the latter is positive. Concerning the nature of the reaction we as yet have no certain knowledge. It is evident that as a result of disturbed nutrition in the pancreas some product is formed somewhere in the body which is capable of being detected in the urine. The most natural supposition is that such a body would be connected with defective carbohydrate metabolism and would stand in some relationship to alimentary glycosuria. It has been learned, however, that the reaction is wholly independent of the diet, so that it must originate in the diseased pancreas itself. But while the kind of food itself has no relation to the reaction the latter does not occur in the fasting state, while it does occur under sham feeding. Therefore, it must be bound up with the active secretion of the organ. The unknown substance which then forms and is eliminated in the urine can be shown to consist in part of a six atom sugar, which does not ferment. When this is boiled gently with HCl the hexose component is changed to phenylglycosazon, with a characteristic melting point, the latter representing the specific reaction. This the author determined under the microscope to be very nearly 200° C. The hexose should stand in some relation to the pentoses normally present in the pancreas.

Changes in the Antitryptic Index in Anaphylaxis.—Rusznyak refers to the discovery that this index is greatly increased in anaphylaxis, and deduces that this fact may be made to throw light on the nature of the latter which he regards as due to catabolic derivatives of protein produced by an abnormally rapid parenteral fermentation. Anaphylaxis is consequently poisoning with peptones. The production of the latter by fermentation is like a trypsin digestion, hence the increase in antitrypsin in the blood which is to be comprehended as an antianaphylaxis which tends to inhibit the parenteral fermentation.

Urinary Pepsin.—Strauss believes the fluctuation in urinary pepsin may be utilized further in diagnosis, especially since the introduction of the urine diastase test to determine the functional activity of the kidneys. Urinary pepsin has now been carefully studied for nearly thirty years and recently the old fibrin test has been supplanted by the recent method. When the urine contains no pepsin it means that the stomach is no longer secreting it, for pepsin is never formed elsewhere in the body.

Insurance Medicine.

Research in Life Insurance.—L. P. Orr, secretary to the Scottish Assurance Company, read a paper with this title at the second sessional meeting of the Scottish Faculty of Actuaries. He said that of late a new interest and a new publicity had been given to the profession of the actuary by recognition by the state of the value of the services which can be rendered to it by actuarial science. In the past the work done by British actuaries had raised their country to the foremost place in actuarial science. The business of a life insurance company was to insure lives, and its duty was to insure these lives on just and equitable terms. While every well managed office did its best to deal reasonably and fairly with applicants, it could do so only according to the knowledge, medical, actuarial, and general, which it possessed. Great progress had been made since the days when an applicant was accepted or rejected according to the impression that his personal appearance made on the assembled Court of Directors, and much had been done in the way of opening the portals of life insurance to those who at one time would have been refused the right of entry. The prevailing system of assessing lives, especially impaired lives, resting though it did on the best medical and actuarial opinion, was capable of improvement by being based to a less extent on individual opinion, and to a greater extent on the more solid ground of statistical experience. No praise could be too great for the painstaking skill and the anxious consideration shown by medical officers, and it was the duty of actuaries to lighten the labors of the physicians by placing them in possession of the important lessons to be learned from research. In the archives of the life offices there were papers to be numbered by hundreds of thousands, containing full particulars of the personal and family histories of each life, and a very considerable proportion of these lives remained on the books until death. It was these papers that under the scrutiny of the actuary and the medical officer could be made to furnish an answer to many problems. It was important to know what were the favorable or unfavorable elements in varying personal and family histories, and no more conclusive knowledge could be obtained than that which the records of life offices could be made to yield. In the past a number of tables dealing with mortality had been made up by medical officers, and some interesting results could be learned from them; but they were of little practical value for the one and only purpose for which they were really needed by insurance companies—namely, the assessing of new entrants. What was wanted was a combination of the best brains of the actuarial and the medical professions to engage in special investigations into the rate of mortality prevailing in various classes and founded on the broad basis to be obtained from combined figures of English and Scottish offices, the object being to assist companies in the initial selection of their risks by increasing their knowledge of the various circumstances which affect longevity. Mr. Balfour had said recently that he was one of those who felt the duty of doing all in their power as a community to encourage that research which was going to make medicine thirty years hence as superior to the medicine of to-day as the medicine of to-day was to the medicine of thirty years ago. That was the position which the Faculty of Actuaries should take up in regard to medical science in its bearing upon life insurance. This point of view raised the subject to a higher plane than when looked at from the purely business position. It was remarkable how one science dovetailed into another, how the discoveries in one helped to the development of knowledge in another. The vast stores of life-histories the insurance companies, and they alone, could draw upon were bound to reveal facts which would have a bearing upon medical science, as had already been shown by limited investigations made in the past. Practically nothing of any value had been done in this country in the way of classifying impaired lives statistically; very little had been done on the Continent; but in the United States a comprehensive investigation had been made, and was now in course of being revised. The belief that such investigations would yield interesting results might be illustrated by the example of applicants who had a pulse-rate below 60. A group of these lives, numbering 12,000, showed at all ages a uniformly favorable mortality experience. As an example of the practical value, from the actuary's point of view, he gave figures relating to lives above the average in weight (also from the American experience); although the lives had been regarded as so good that any objections on the ground of weight were overruled, yet in the largest group, consisting of over 26,000, the deaths were 47 per cent. above the number expected, and for lives entering above age 45 the excess mortality was no less than 72 per cent. The lessons to be learned from such research as he pleaded for should be made public, so that they might become known to the members of the medical profession generally, and through them become available for the benefit of all. To obtain successful results the English and the Scottish offices must collaborate, and he advocated the establishment under their joint auspices of a bureau of research, well equipped actuarially and medically. The bureau could work for the future as well as for the present by accumulating statistics to be used when sufficient data had been obtained to form a broad enfarch basis. Any objection on the score of cost should be put out of court at once; British offices counted their income by tens of millions, their funds by hundreds of millions, and in comparison the cost would be microscopic. He did not seek to minimize the amount of work involved in such research or the difficulties in pursuing it; but the Faculty of Actuaries, by virtue of its royal charter, was the custodian of the science in Scotland, and he hoped that in this movement in the evolution of life insurance it would take a leading part, believing it to be in its power to confer benefits not only upon the business of insurance but upon medical science and upon the community at large.—*British Medical Journal*, December 16, 1911.

A Victim of 200 Accidents.—The London correspondent of the *Journal of the American Medical Association* cites the case of a man, aged thirty-seven, who pleaded guilty to obtaining money by false pretences from tradesmen. He would fall down and claim to have been injured through the negligence of the persons whom he made his victims. His deception was favored by a malformed wrist which he represented as due to the accident. As he generally claimed only a modest amount his victims paid rather than fight the case, which, even if they were successful, would have involved them in much greater cost. If the cases had come into court he would soon have been detected. As they did not, the deception continued. During three years he successfully made about 200 such claims. He was arrested through playing the same trick on two butchers on the same morning, alleging that he had fallen on pieces of fat outside their shops. The fact that both at once sought the assistance of the Incorporated Society of Meat Traders led to detection of the fraud. A confederate accompanied him, making notes on his behalf of the incident with particulars of the name and address of those from whom the money was to be obtained. He was sentenced to eighteen months' hard labor.

Missouri Forbids Insurance Against Carelessness.—State Superintendent of Insurance Frank Blake has issued an order to insurance companies which insure physicians, dentists, surgeons, and druggists against liability for carelessness, and automobile owners against liability for injury to persons or property, to cease writing this form of insurance in the State of Missouri.

Book Reviews.

THE AMERICAN YEAR BOOK. A Record of Events and Progress, 1911. Edited by FRANCIS G. WICKWARE, B.A., B.Sc., Under Direction of a Supervisory Board Representing National Learned Societies. Price, $3.50 net. New York and London: D. Appleton & Company, 1912.

THIS second volume of the American Year Book, a publication begun in 1911, is constructed on the same general plan as its predecessor, though it is an improvement upon that volume in several respects. The societies under whose general supervision, as exercised by a board of their members, the work is prepared number 38. The members of this board either prepare the material themselves or designate some one to do the work under their supervision, consequently the information presented may be regarded as authoritative.

The work is one that admirably meets the wants of research workers and others who may need to inform themselves of the happenings in any special branch of man's activity. The main topics covered are: Comparative statistics, history and politics, government, economic and social questions, public works and national defence, industries and occupations, science and engineering, the humanities, and current record. Under these are upward of forty subtitles; under "Science and Engineering," for example, are grouped mathematics and astronomy; geology, meteorology, terrestrial magnetism, and geography; chemistry and physics; the organic sciences; psychology and philosophy; medicine and surgery; engineering. The articles in the subsection on medicine and surgery, contributed by Alexander and Adrian Lambert of New York, are: Typhoid vaccination, syphilis, protozoan culture, circulation in the peripheral mechanism of the body, the micrograph, the heart, fractures, transfusion of blood, administration of ether, internal hydrocephalus, esophagoscopy and gastroscopy, papillary growths of the urinary bladder, and x-rays. The information contained in these contributions is brought well down to the end of 1911, one of the references being to an editorial article in the MEDICAL RECORD of November 25, 1911. It is not for information in medical topics only, or chiefly, that the medical reader will find this work of especial use, but to obtain knowledge of work in other departments of human endeavor. If his wants in respect of other branches can be as satisfactorily met as the need of the layman for information in medical progress, the labor of the editor and his staff of contributors will be amply justified.

DISEASES OF THE DIGESTIVE CANAL (Esophagus, Stomach, Intestines). By Dr. PAUL COHNHEIM, Specialist in Diseases of the Stomach and Intestines in Berlin. From the second German edition. Edited and translated by DUDLEY FULTON, M.D., Assistant Professor of Principles and Practice of Medicine, University of California College of Medicine, Los Angeles Department; Attending Physician, Los Angeles County Hospital. Illustrated. Second Edition. Price $4.00. Philadelphia and London: J. B. Lippincott, 1911.

THE clinical viewpoint is the one from which this book has been written. The value of the anamnesis is emphasized, and those aspects of gastroenterology which present themselves in the everyday work of the practitioner are clearly and succinctly set forth with the skill that only the experienced teacher can command. The simplicity and directness of the text, the didactic arrangement of the subject-matter, the illustrative case histories, and the numerous prescriptions are all striking features which characterize this, as well as the first edition. In the present edition the editor has emphasized the increasing value of skiagraphy, and has included recent improvements in the methods of diagnosing lesions of the esophagus, a discussion of acute dilatation of the stomach, the treatment of gastric and duodenal hemorrhage, and the technique of sigmoidoscopy.

DEVELOPMENTAL PATHOLOGY. A Study in Degenerative Evolution. By EUGENE S. TALBOT, M.S., D.D.S., M.D., LL.D., Professor of Stomatology, Bennett Medical College (Loyola University); Corresponding Member, Budapest Royal Society of Physicians; Honorary President International Association of Stomatology, 1907, Paris. With 346 Illustrations. Price $6.00. Boston: Richard E. Badger, The Gorham Press, 1911.

THE main objects of this book are to show that the ontogeny of man, his structure and organs, is a modified recapitulation of his phylogeny in development. The author contends that, as the vertebral phase appears early in embryogeny, an unstable nervous system, checked by parental defects, eruptive fevers, and other agencies at the periods of stress in the child, affects phylogeny and ontogeny. He seeks thus to correct certain erroneous conceptions of heredity by showing that neither excessive nor arrested development is inherited directly from the parent. Dr. Talbot points out by the aid of developmental pathology that degenerative evolution and phylogeny or that process by which an individual or structure is transformed from a lower to a higher type are always going on, and that this fact, if one would obtain a proper grasp of the situation, must be considered in conjunction with heredity. In short, intrauterine education, environment, and development are quite as important as heredity in fashioning the individual and the race. The book is well printed and illustrated and deals with a most interesting subject in an instructive way.

HEREDITY IN RELATION TO EUGENICS. By CHARLES BENEDICT DAVENPORT, Carnegie Institute of Washington, Director Department of Experimental Evolution, Cold Spring Harbor, Long Island, N. Y.; Secretary of the Eugenics Section American Breeders' Association. With 175 Illustrations and Diagrams, and Complete Bibliography and Index. Price $2.00 net. New York: Henry Holt & Co., 1911.

IN these days of city dwelling and the degeneration of the human race following this mode of life, the question of improving the stock, physically at any rate, is much to the front. Works on heredity and eugenics have been fairly frequent of recent years, but the matter is as yet little understood except by the few. In the book before us the author has endeavored to make clear the various complex and perplexing problems in connection with heredity and eugenics, and it may be said that his attempt has been as successful as might have been anticipated. Perhaps he is somewhat too inclined to beg the question and to attribute to heredity more physical and mental ills than the greatest authorities have allowed themselves to attribute. There can be, however, no cavil as to the statements made with regard to the inheritance of certain physical and mental traits. The influence of breeding from healthy stock is as evident in man as in other animals and Mr. Davenport proves this point by citing the example of numerous American families. There is no doubt that measures are needed in all civilized countries to counteract the bad effects of modern industrial life and of overcrowding in cities, and if the application of eugenics will aid in gaining this end it should certainly be practised as far as possible. Enough is not yet known on the subject to state that it is practicable and the author himself admits that further investigation is required. The book is well compiled and affords a considerable amount of information couched in lucid language.

A TEXT-BOOK OF PHYSIOLOGICAL CHEMISTRY. By OLOF HAMMARSTEN, Emeritus Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Author's Enlarged and Revised Seventh German Edition by JOHN A. MANDEL, Sc.D., Professor of Chemistry in the New York University and Bellevue Hospital Medical College. Sixth Edition; Total Issue, Nine Thousand. Price $4.00 net. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1911.

THE chemistry of animal and plant tissues and of the vital processes taking place in living bodies is a comparatively new science and one which, though great strides have been made in it in the last decade, offers one of the most promising fields for discovery for the student and laboratory worker. Of the many treatises on physiological chemistry which have appeared in the past six or seven years none has proved its superiority to Hammarsten's, and none, we venture to say, has been a greater favorite with the army of students who have turned their attention to solving the manifold chemical problems furnished by the processes of metabolism in the human body. The seventh German edition, of which this is a translation —excellently done it is—appeared about two years ago. It contains a new chapter, written by Professor S. G. Hedin of Upsala, on "Physical Chemistry in Biology." The sections into which this chapter are divided are Osmotic pressure, Colloids, Catalysis, Enzymes, and Ions and Salt action. The popularity of this work among English-speaking students of animal chemistry is shown by the fact that the American editions follow the German ones with great regularity, this being the sixth American, corresponding to the seventh German, edition. Professor Mandel has done his part well and has made a smooth and idiomatic translation, free from all German expressions or turns of phrase. It is scarcely necessary to recommend this work to students of biochemistry; they already know its worth, and all that is necessary to tell them is that a new edition has appeared.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 22, 1912

THE PRESIDENT, DR. JAMES F. MCKERNON, IN THE CHAIR.

Address of the Retiring President.—Dr. JAMES F. MCKERNON thanked the members for the support they had given to the society during his term of office. Some radical changes had occurred during the year and one was limiting the executive session to one-half an hour, except when such business of importance might present itself as to call for an extension of time by a majority vote. The society was to be congratulated upon the accessions to its membership during the year. No one who had not been closely identified with the official workings of the society could appreciate in the slightest degree the enormous amount of detail work carried on; and the members owed Mr. Vandiver and his staff their deepest appreciation of the manner in which they have and were now conducting the legal department of the society.

Inaugural Address of the President-Elect.—Dr. CHARLES GILMORE KERLEY expressed his appreciation of the high honor that had been conferred upon him and assured the members that he was not unmindful of its duties and responsibilities. The work of the legislative committee was to keep in touch with medical legislation, to inaugurate that which seemed desirable, to promote that which was beneficial, and to obstruct that which was vicious. During the past year charlatans, illegal practitioners of medicine, proprietors of so-called medical institutions, and members of various cults illegally dealing with things medical had been brought to the bar of justice. Without this activity on the part of the society, without this protecting influence for the public good, the city of New York would be overrun with those who preyed upon the ignorant among all classes of society. This branch of the society as a public benefactor was of no little importance. Dr. Kerley called attention to the effective educational work that was being done by the public health educational committee of the American Medical Association. Since the organization of this work, in July, 1909, over 5,000 lectures had been given to audiences aggregating 330,000 persons. The most difficult and disagreeable subject of medical charities, particularly the abuse of medical charity, was to be considered. The State rightly insisted that medical men should be well qualified, and in their medical societies they established high standards of honor and professional conduct. When so much was required it would seem but fair that an effort be made in order that those who met those requirements be given the opportunity for a reasonable return. The medical profession did more work without compensation than all the other professions combined. A considerable portion of the public had been educated to feel that medical services were due them without price. Physicians had cheapened their profession in the eyes of the public, and they were cheapening it every day by bidding for work through medical charities. Hundreds of physicians to-day in the city of New York were barely earning a poor living; not because they were not qualified; not because they were not willing to work; not because there were no sick to be treated; not because of the existence of various cults and societies which dealt with things medical. These qualified physicians were deprived of a reasonable living because of the medical charities as represented by hospitals, dispensaries, and other societies, lodge physicians, and contract practice, where those afflicted could be treated for little or no compensation when they were well able to pay. With hospital, dispensary, and other societies striving for patients, they should not expect the community to put a high value on what they were so anxious to give away. Sixty per cent. was a low estimate of those who could pay for medical services who were now getting it free. In twenty per cent. of this number it would be difficult to determine whether or not they were deserving of free treatment. The remaining forty per cent. were composed of people who were not poor, and many enjoyed larger incomes than the physician who was treating them. The constitution of the State provided in Article VIII, in Section 11, that any person who obtained medical or surgical treatment on false representation from any dispensary should be guilty of a misdemeanor. How many at the present time were given an opportunity to make false representations, and how many had been brought to court on this charge? Was it fair to the young medical man that he should be required to devote his time and energies to the care of the poor of the State without compensation? Physicians should be compensated for dispensary work. The nurses who might be employed were paid, the registrar was paid, and even the scrub woman was paid. All received compensation except the physician. The present system of medical service through contract work, such as the care of members of lodges and their families, orders of whatever society, cheapened medical service, degraded its purpose, and gave very inadequate service to the supposed beneficiaries, and the patients were the losers. The fee-splitting evil was most openly practised, and it was the means of these lodge doctors obtaining an income; was it desirable for the Medical Society of the County of New York to attempt control of this matter? Legislation relating to the establishment and location of medical institutions was greatly needed. There was at present a decided tendency to centralize medical charities within a comparatively small acreage on the East and West Side of the city, between Forty-second and Sixty-second streets. Such centralization, particularly of outdoor departments, meant that all who applied would be treated, an increased abuse of medical charity. The Society of the Federation of Churches in New York City in 1905, and again in 1910, took a careful house-to-house census of the population of this district; it was found that in 1910 there were 11,160 fewer residents than in 1905, a diminution of density of population of more than twenty per acre of acreage. Two organizations were making an investigation at the present time with the idea of establishing control relating to the distribution of medical charities and, if necessary, the Medical Society of the County of New York should cooperate. Probably no city had a more efficient department of health than the city of New York. In its efforts in behalf of the public it was well to call the Health Department's attention to the fact that much care should be exercised in order that it did not contribute its share to the abuse of medical charity. To what extent the Health Department should practise medicine was a matter that should be definitely determined. Section 1170, Greater New York Charter, as amended by the laws of 1909, chapter 342, stated that the Board of Health might cause proper care and attendance to be given to persons when it should be made to appear to the Board of Health that any such person was so poor as to be unable to procure for himself such care and attendance. There should be some means of regulating medical charities and there should be cooperation in this among the various medical bodies. Desirable legislation had often failed because of lack of unanimity on the part of physicians. In conclusion, Dr. Kerley suggested that the Comitia Minora be empowered to remit the annual dues of any member who was old and poor so that he might not be forced to resign. It seemed most desirable that the statute of 1806, adequate 106 years ago, be changed so that it might meet the necessities of 1912, and in this statute unprofessional conduct should

be incorporated and defined. There should be some means of control of hospital, dispensary, and medical charities, either by increasing the power of the State Board of Charities or through the establishment of a commission to which these organizations should be responsible.

Dr. E. Eliot Harris moved that the suggestions contained in Dr. Kerley's address be referred to a committee of five who should be instructed to report at a subsequent meeting. This was unanimously carried.

Trachoma: Its Cause and Treatment.—Dr. L. W. Crigler read this paper. He said that trachoma was a disease of the conjunctiva in which there was a characteristic connective tissue hyperplasia. It was marked by a proliferation of lymphoid cells, the follicles thus formed tending to degenerate and to become encapsulated by the newly formed connective tissue. As a result of this inflammatory process newly formed blood-vessels penetrated these follicles, which became distended with fluid and pushed their way above the surface of the conjunctiva; finally becoming degenerate, they broke down and the overlying conjunctiva was replaced by scar tissue. Thus, step by step, the entire conjunctiva was destroyed. As a result of this chronic inflammatory process connective tissue changes took place in the deeper structures of the lid, normal blood-vessels became obliterated, all glandular secretion was checked, and a general atrophy of the lid was produced. There was no doubt as to the contagiousness of trachoma. For the past one hundred years it had been one of the problems of military hygiene in the armies of Europe. Wherever large bodies of men were congregated, where there were intimate contact and foul air, rapid dissemination was certain. In this country those living in the tenement districts of large cities were in constant danger of infection. The violence of the onset seemed in some way related to the environment of the individual, bad hygienic conditions being directly conducive to the more aggravated types. Improved methods of sanitation had done much to minimize the frequency of epidemics of this disease, and except in hotbeds of trachoma acute onset was unusual. Little was known of the etiology of this affection. Work done in this direction centered about the so-called trachoma corpuscles, or trachoma bodies, which were first described by Halberstaedter and von Prowaczek in Java, and almost simultaneously Prof. Greeff and his coworkers succeeded in finding and describing similar bodies. These corpuscles had been found not alone in trachomatous eyes, but in eyes entirely free from any evidence whatsoever of trachoma. Fleming found them associated with gonococci repeatedly in connection with ophthalmia neonatorum. They had been found at times in the gonorrheal urethra of both males and females. Their origin being so obscure and their morphology so varied had led some investigators to consider the question as to whether they were dealing with a microorganism, a parasite, or a degenerate cell. These bodies had not been isolated and efforts to obtain them in pure culture had been unsuccessful. The consensus of opinion, however, was that they had some pathological significance in relation to trachoma. They were found in the conjunctival epithelial cells, where they presented the appearance of minute diplococci situated in the protoplasm of the cell. The writer said that one point he wished to emphasize was that trachoma was essentially a chronic disease, and that, with each succeeding month of its duration, new features arose to annoy and harass the unfortunate individual. Years, as a rule, elapsed between the time of its incipiency and the terminal stage, cicatrization, and unless the patient was so fortunate as to have the disease arrested early by intelligent treatment partial impairment of the sight or total blindness was the result. The clinical picture of the chronic type of this disease showed a slight drooping of the upper lids, which appeared thicker than normal, while the palpebral conjunctiva of both lids was studded with numerous translucent lymphoid follicles, varying in size from a pinhead to a grapeshot. In the early stage these follicles were confined to the retrotarsal fold of the upper lid, and it had to be doubly inverted before they could be seen. Dr. Crigler referred to the great similarity between trachoma and follicular conjunctivitis, and deplored the fact that there was no diagnostic point that would enable the general practitioner to distinguish them, to say nothing of the difficulty which the specialist encountered in separating these two diseases. The only distinguishing point seemed to be that follicular conjunctivitis tended to spontaneous recovery, leaving a normal conjunctiva, while trachoma never did. All doubt of the diagnosis was laid aside when the disease reached its second stage, where there was a hypertrophic thickening of the conjunctiva associated with a beginning destruction of the lymphoid follicles and a deposition of fibrous tissue. Months might be passed in reaching this stage. Pannus always began in the upper half of the cornea; no doubt the friction of the upper lid had a great deal to do with bringing about this condition, though infection also might have something to do with it. The acute type of trachoma differed from the chronic only in that the onset was sudden, the patient having symptoms of violent ophthalmia, with photophobia, lacrymation, and a free discharge of thin scropus. There had been no advance in the medical treatment of trachoma in the past ten years. The remedies used, however, were not without effect. The great stumbling block in the way of a cure was the patient himself, who failed to follow the advice of the physician, not realizing the importance of regular and systematic treatment lasting over a long period of time. The two main remedies depended upon to combat the inflammation and to lessen the hypertrophy were silver nitrate and copper sulphate, the former where there was much secretion, and the latter where there was marked hypertrophy. Both were extremely and persistently painful. Expression was indicated in those cases of trachoma that presented numerous follicles in the retrotarsal folds as well as on the palpebral conjunctiva. This operation did not bring about a cure of trachoma; it only lessened congestion and made the application of remedial measures more effectual. He felt convinced that all cases that responded to expression and a few weeks' after-treatment were not trachoma. They should never fail to emphasize to the patient the necessity of long-continued after-treatment; neglect to pursue this course of after-treatment was responsible for many relapses. If the disease was allowed to progress into the hypertrophic stage, with beginning cicatrization, successful cure became impossible and a resort to surgical measures was the only method of relief remaining. The surgical treatment as outlined by Hiesrath of Königsburg, and later modified by Vossius and Kühnt, had not received the recognition that it deserved. These men observed in old cases where a cure had been brought about by Nature a complete obliteration of the retrotarsal folds, a shrunken and distorted cartilage, a pannus that was dense and permanent, a complete destruction of all follicles, and a dry and shrunken conjunctiva. They argued that, as the disease would not subside until the tissues involved were destroyed, why not remove them at once and save the patient the time and suffering which nature took years to accomplish. The two operations indicated in advanced cases of trachoma were: first, a removal of the tarsal cartilage of the upper lid together with its overlying conjunctiva and retrotarsal fold, and, secondly, a removal of the tarsal cartilage of the upper lid alone. The former procedure was indicated in the beginning of the cicatricial stage, where roughened and ulcerated follicles remained; the latter where the follicles had been replaced by connective tissue, and the cartilage, while still hypertrophied, was undergoing retrograde changes

which resulted in a distortion of the lid. The operation of removing both the cartilage and conjunctiva was termed combined excision and was briefly described as follows. The upper lid was doubly everted by means of fixation forceps and horn. A horizontal incision was made through the conjunctiva alone at the junction of the ocular and palpebral conjunctiva. The cut margin of the bulbar conjunctiva was slightly undermined and three sutures were passed equidistant, sufficiently long to admit of a needle at each end. The lid was then singly everted and another incision 2½ mm. from and parallel to the lid margin was made through conjunctiva and cartilage. The ends of the incision were made to unite with the posterior one, and the conjunctiva and cartilage were gently dissected away, care being taken not to remove any of the tissue beneath this cartilage and to leave a very thin strip of cartilage above, if possible, to prevent injury to the levator muscle. The three sutures placed in the bulbar conjunctiva were drawn forward and, each being armed with two needles, were passed from within outward, one end passing through the cut end of the cartilage, the other just posterior. This caused coaptation of the bulbar conjunctiva with the 2½ mm. strip of conjunctiva remaining. The fornix was obliterated. The sutures were tied over a wick of gauze. The results of a hundred or more of these cases operated upon by Dr. Wootton, the writer, and various members of the staff of the Manhattan Eye and Ear Hospital during the past two years demonstrated beyond a doubt that this was the most successful means known of combating this condition. They had obtained a percentage of cures of at least 75 per cent. A resort to torsal resection alone was less frequent and the results, when the operation had not been done until late in the course of the disease, less gratifying. In making tarsal resection the lid was everted, an incision was made through conjunctiva and cartilage 2½ mm. from and parallel to the lid margin, the cartilage was carefully dissected away both anteriorly and posteriorly and the conjunctiva sutured in its original position in a manner similar to that described in the preceding operation. Neither of these operations restricted the motility of the eyeball, nor interfered with movement of the lids. It relieved ptosis and entropion and produced no outward deformity further than a fold in the lid sometimes more than normal. If granulations sprang up in the line of incision they might be removed with a strong solution of silver nitrate. Trachoma of the lower lid did not lead to the bad results that were produced when it attacked the upper lid. Removal of the palpebral conjunctiva alone was here indicated since the disease did not seem to involve deeper structures. Removal of the tarsal cartilage in the lower lid would result in immediate entropion.

Dr. Herbert W. Wootton said that the milder tyes of follicular disease really required no treatment. He called attention to another type that occurred in children in which the disease was most marked upon the upper lid and this could be treated with astringents, but not with long-continued treatment by caustics. It was a papillary conjunctivitis with much hypertrophy of the conjunctiva. These cases were often called trachoma. He said he had seen only two cases of this type in which there was corneal involvement.

Dr. Ellice M. Alger said that our great need was some means of differentiating between trachoma and follicular conjunctivitis, which were much confused even by ophthamologists. The term trachoma was originally applied to all diseases characterized by a rough or granular lid. The microscope had enabled them to narrow this application materially, but it was still too indefinite. At present they recognized two distinct types of trachoma, one marked by true hypertrophy of the conjunctiva and the other simply by the presence of enlarged follicles or glands. He did not believe the first form was ever cured by any method of treatment. It lasted a lifetime and the patient was fortunate to have his conjunctiva replaced by a smooth cicatrix. The only thing treatment could accomplish was to hasten this process. Follicles alone, however, without true hypertrophy of the conjunctiva, were not enough to make a diagnosis of trachoma, since they were merely the reaction of the conjunctiva to irritation, whether of a chemical, bacterial, or mechanical nature. Among school children who were predisposed to enlarged lymphatics, as shown by their adenoids and cervical glands, follicular conjunctivitis was extremely common, while true papillary trachoma was very rare. Such children suffered little discomfort, were not sources of danger to others, and would get absolutely well in time whether treated or not. To apply operative measures to them was not only illogical, but often actually harmful.

Dr. A. Edward Davis said that we were still in doubt as to a bacteriological diagnosis, although the trachoma corpuscles of Halberstaedter and von Prowaczek were supposed to be the true cause of trachoma. And recently Robert Hesse found these corpuscles in the epithelium of the lids, the conjunctiva of the eyeball, and in the diseased cornea in a case of old trachoma with pannus and considered it as a proof of the specific pathogenesis of trachomatous pannus. Be that as it might, the fact remained that they were still in doubt as to the true cause of trachoma, and must rely, in the majority of cases at least, on a clinical diagnosis. The most reliable symptom of true trachoma was the formation of firm organized follicles, which coalesced with the conjunctiva, broke down, and caused its progressive destruction. And this feature they must rely upon for a diagnosis. The author of the paper said he relied chiefly on silver nitrate and copper sulphate. Dr. Davis had come to rely largely on another remedy in these cases. He used sulphate of zinc, not in the strength ordinarily advised in the textbooks, but solutions of 2 per cent., 3 per cent., and 4 per cent., according to the severity of the case, applying it with cotton wound on an applicator. It did not burn or hurt so much nor nearly so long a time as either silver or copper, and was just as effective in hastening a cure. Dr. Crigler expressed the opinion in his paper that he doubted if the "expression operation" ever *cured* a true trachoma. Dr. Davis's experience, which had been large in such cases, was just to the contrary. He thought he knew a true trachoma, that was as well as they could know it clinically by the firm granulations with the adherent conjunctiva, and in a great number of these cases he had given complete relief in from two to six weeks' time. Certainly the "expression treatment," or cure, was infinitely shorter in time than local applications, and the patient did not become discouraged and quit treatment, as was so often the case with local treatment. The invention of the Knap roller forceps, to say nothing of the other less effective forceps, had been of incalculable value in shortening the treatment of trachoma, placing patients back in school or at work in a few weeks' time, whereas before the introduction of the "expression operation" it required months and even years to accomplish the same result. He therefore made a strong protest against minimizing the value of the "expression operation" in the treatment of trachoma. As to the operative measures in the later stages of trachoma, he believed the Heisrath operation the best one, and certainly justifiable in so grave a condition. A very recent contribution to the subject of treatment of trachoma was that of Jacovides, Egypt, printed in the current issue of *Ophthalmology*. His experience had been very large. It was half surgical and half medical. First, he did expression in the early stages. Later grattage, and lastly curettage with Abadie's sharp curette of isolated follicles and granulations. Secondly, the medical treatment consisted in applying silver nitrate to the

lids the day following the operation and for six or eight days until all secretion stopped. After the active secretion stopped (during the stage of active secretion the lids and eyes should be bathed frequently—every two to four hours) he made applications of copper sulphate solution in glycerine daily. At the end of fifteen to twenty-five days cicatrization began and the patient was soon well. Dr. Jacovides had carried out this treatment in fifteen thousand cases and had been greatly pleased with the results. Only about 8 or 10 per cent. had recurred, and these chiefly in children. In these latter cases he thought it was *reinfection* and not recurrence

Dr. John E. Weeks said he had not seen very good results after the Heisrath operation in cases of advanced trachoma. Any operation that lessened the area of the conjunctiva was a faulty one and should not be indulged in. The area of the conjunctiva should be maintained. With regard to the application of silver nitrate and copper sulphate to the conjunctiva after the expression operation, he believed that this was unnecessarily painful to the patient and brought about unsatisfactory results. The relapses that occurred in the treatment of trachoma were due to imperfect antisepsis.

Dr. L. Anna W. Williams said that in all cases of papillary trachoma, however slight the secretion, the New York Department of Health had found simultaneously with the "trachoma inclusions" a tiny hemoglobinophilic bacillus which, in its cycle of development, was exactly similar to that of the "trachoma inclusions" as described by Prowaczek and others. The bacillus seemed to be closely allied to that of influenza and the Koch-Weeks bacillus. This made the question of the relation of trachoma to acute contagious conjunctivitis of greater importance than they had hitherto considered it. Neither these organisms nor the inclusions had been found in cases of folliculosis. On the strength of these results the Health Department, in conjunction with the Department of Education, was attempting to establish special mixed classes for those children who were now being sent to school with slight secretions while receiving treatment at clinics. The Health Department was following up closely with full written records a large series of cases and it hoped at a later date to be able to have evidence on a number of hitherto disputed questions relating to trachoma.

The Cause of Myopia.—Dr. William H. Bates said that wild birds had usually good distant vision; in captivity they acquired myopia. Uncivilized people had good sight, but after living in civilized communities they acquired myopia. New-born children had normal eyes under atropine; but for some months or years later functional myopia was demonstrated with the aid of retinoscopy. An unsuccessful effort of the normal eye to see accurately new, strange, or unfamiliar objects was always followed either by myopic astigmatism, compound astigmatism, or simple myopia. In most eyes with errors of refraction and in normal eyes with eccentric fixation the axes of astigmatism produced by efforts to see distant objects were not usually constant and greater variations occurred in the same eyes from day to day than were observed in normal eyes. In compound hypermetropic astigmatism the effort to see at a distance always lessened the refraction of sometimes one, sometimes other principal meridians. In compound myopic astigmatism one or both of the principal meridians were always increased. In mixed astigmatism sometimes the hypermetropic meridian was lessened. In other cases the myopic meridian was increased; and in still others the hypermetropic meridian was lessened, while the myopic meridian was increased. In one class in one public school in the city of New York there were thirty young pupils; the attention of the teacher was directed to five children whose facial expression suggested defective vision. Their sight was tested and found to be poor in all. These children were shown how to read the small letters on the Snellen card and they obtained normal vision and required no glasses. The facial wrinkling and the evidences of strain disappeared. Cases were reported to illustrate the effects of effort when reading with difficulty at a near point. The uncivilized man was compelled to adjust his eyes for accurate distant vision for protection against enemies and in obtaining food. But when living in civilized communities he was protected from enemies, his food was supplied, and soon accurate distant vision was no longer necessary; the civilized man neglected to adjust his eyes for accurate distant vision and therefore he became myopic. School children did not need accurate adjustment of their eyes for distant vision. In conclusion Dr. Bates said the myopia was not caused by efforts to read by a bad light; the cause of myopia was an effort to see distant objects.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 18, 1912.

The President, Dr. Wm. M. Polk, in the Chair.

This meeting was held under the auspices of the Section on Medicine, and consisted of contributions from the hospital of the Rockefeller Institute for Medical Research.

The Nature of the Intoxication in Pneumonia.—Dr. Rufus I. Cole said they had been investigating this subject of pneumonia along three lines, the question of infection, the nature of the immunity, and the nature of the intoxication. All agreed that in pneumonia a severe general intoxication was present, and it was generally accepted that the degree of intoxication was quite independent of the degree of lung involvement, and that the intoxication was not directly related to the mechanical disturbance of respiration due to the lesions in the lungs. It was quite conceivable that the whole effect of the pneumococcus was in inducing the local lung lesion, and that the general symptoms which supervened had only an indirect relationship to the pneumococci, the symptoms being due to the absorption of the products of the inflammatory reaction. It was well known that fever and constitutional disturbances might arise from sterile abscesses, even from the absorption of extravasated blood. It was hardly likely, however, that the specific and characteristic symptoms in pneumonia could be due to this cause. The metabolic studies of Frederick Müller gave evidence that the pulmonary exudate during the course of a pneumonia was constantly being absorbed and reformed. This exudate might be toxic. In any case, the relation between the bacteria and the irritation of the tissues, resulting in inflammatory exudate, had to be explained. If the pneumococcus did not act in a purely mechanical way by its presence, one must suppose that it acted through definite chemical substances arising from it, or else in some mysterious way through physical forces such as disturbances of surface tension or withdrawal from the cells of some necessary constituents. The endotoxin theory of Pfeiffer had come to be generally employed to explain the nature of the intoxication induced by the pneumococcus. This presupposed that toxic substances were present within the bodies of the bacteria which, however, were set free only upon the breaking up or dissolution of the bodies of the bacteria. There was no evidence that pneumococci during growth elaborated a poison, as did the bacilli of diphtheria and tetanus, although the most diverse media and methods to produce such a poison had been employed. The statement had been made that the blood of pneumonia patients, when injected into rabbits, might produce a profound intoxication. It was now known that this blood contained the bacteria, and some of the results which followed were properly due to infection. Normal human blood was not infrequently toxic for rabbits. A rabbit

was inoculated with an overwhelming dose of the pneumococci, and just before death occurred (in from five to eight hours) the animal was bled to death, the blood was defibrinated as quickly as possible, the serum was passed through a Berkefeld filter to remove the bacteria, and as quickly as possible the filtrate was injected into a normal rabbit; to their surprise the animal did not die. The negative experiments made showed that the toxin, if formed in the blood, was either neutralized or fixed as soon as formed, or that it was changed and rendered non-toxic during the time necessarily elapsing while the serum was separating and being filtered. Then they turned their attention to the so-called anaphylatoxin of Friedberger and applied this method to the detection of a toxic substance in the pneumococcus, as had already been done by Neufeld and Dodd. They succeeded in repeating his experiment with the pneumococcus, and in a large number of guinea-pigs sudden death was produced with symptoms identical with those in anaphylactic shock following the injection of other proteins. Friedberger thought this experiment might offer the explanation for all bacterial intoxications. Rosenau, working with the pneumococci, had succeeded in producing a similar acute reaction and death by the injection of bacteria which had not been treated by immune serum and complement, but simply mixed in normal salt solution and allowed to undergo autolysis for forty-eight hours. He drew the conclusion that the virulence of pneumococci depended upon the readiness with which they autolyzed. Against this view there were many facts and among them was that the readiness to autolysis was not a strictly parallel property to virulence. Among about 250 guinea-pigs injected, acute death resembling that seen in anaphylactic shock had only been seen in seven instances. While they were unable to confirm Rosenau's results in producing typical anaphylactic shock with great uniformity with pneumococci autolyzed for forty-eight hours, they did find that a large number of the animals injected intravenously with autolyzed pneumococci died in from two to twelve hours with characteristic pathological lesions. The toxicity was not directly proportional to the bacterial concentration. The concentrations employed were from 500 million to ten billion per cubic centimeter. An important fact was that autolyzed extracts of pneumococci did contain toxic substances for guinea-pigs, and the toxicity apparently had a relation to the digestion of the bodies of the bacteria by the ferments contained within them. A further study of these toxic substances produced both *in vivo* and *in vitro* would undoubtedly lead to further knowledge concerning the nature of pneumonia and aid in solving the problems relating to the cure.

The Action of Pneumococcus Serum.—Dr. A. R. DOCHEZ presented some charts showing the results of the action of the pneumococcus serum in animals.

Dr. ISAAC ADLER told of some experiments that were made several years ago in testing the toxicity of the blood in cases of pneumonia in its different stages and kinds. Experiments were made upon the effect upon turtles' hearts; the results were never published because the heart never responded.

The Pathology of Acute Poliomyelitis.—Dr. FRANCIS W. PEABODY read this paper. He said that the attention of observers who had considered the pathology of poliomyelitis had been almost wholly centered on the lesions of the central nervous system, but in view of the very definite and constant changes which were found at autopsy in other viscera it was rather strange that they should have been almost wholly disregarded and that so little emphasis should have been put on the fact that acute poliomyelitis was essentially a general infection. Rissler, Strauss, Harbitz, Scheel, and Wickham had all noted the presence of lesions outside the nervous system, but had passed them by as having little bearing on the disease. As a matter of fact, the recognition of acute poliomyelitis as a general infection had an important bearing both in explaining the course of the disease and as affecting any possible means of treating it. While the exact path by which the virus entered the body was at present not definitely known, there was clinical and experimental evidence which made it probable that infection frequently gained entrance from the upper respiratory tract. It had been shown by Flexner, both anatomically and experimentally, that the upper nasal cavities were in direct communication with the meninges by means of the lymphatics, which passed outward with the filaments of the olfactory nerve. The earliest change which had been described in the nervous system was hyperemia and the collection of numbers of small mononuclear cells, probably lymphocytes, in the perivascular lymph spaces of the blood-vessels of leptomeninges. The first change, then, was an acute interstitial meningitis, which was not associated with fibrin formation or with exudate on the surface of the meninges. The blood supply of the cord was derived from the vessels of the meninges, and this perivascular infiltration followed along the vessels as they entered the cord from the meninges. Thus the earliest change which was found in the cord itself, both in human beings and in the experimentally produced disease, was hyperemia and the collection of small, round cells in the lymph spaces surrounding the vessels. This cellular exudate formed a sheath apparently completely surrounding the vessels for long stretches and in many places the cells were so numerous that they formed thick collars, which seemed to press on the lumen and might thus obstruct circulation. It was probable that there was also some toxic or mechanical effect in the intimal lining of the vessels, for hemorrhages, minute or extensive, were frequent findings, and one of the prominent features of most cases was the extensive edema. These three factors, cellular exudate, hemorrhages, and edema, all of them dependent upon vascular changes, might be regarded as the primary reaction of the nervous system to the virus of poliomyelitis. It had been suggested that the process by which the vascular lesions affected the nerve cells might be essentially a mechanical one. If the hemorrhage and exudate were absorbed soon enough, the cells might recover their function, but if, on the other hand, the anemia and pressure had been prolonged and excessive the nerve cells went on to complete necrosis. Histological examination showed nerve cells in all stages of degeneration. A most striking picture was formed by the entrance of polymorphonuclear neurophages into the necrotic nerve cells. In more severe lesions hyperemia, perivascular infiltration, hemorrhages, edema, and diffuse cellular infiltration throughout the gray and white matter were observed, but nerve cells might be completely absent from the picture. The same sequence of changes was practically constant in the posterior root ganglia and was found to a less degree in the brain, medulla, and pons. The changes which were found in the other organs in acute poliomyelitis were less striking than those in the nervous system, but they were practically as constant. In all of the eleven acute cases which they had examined there had been more or less extensive involvement of the lymphoid tissue and of parenchymatous organs. The lymphoid tissue throughout the body appeared to react to the virus. The Peyer's patches of the intestine and the mesenteric lymph glands showed perhaps the most marked acute swelling, but the mucosa over the Peyer's patches was unaffected. There was also definite and sometimes pronounced enlargement of the substernal, bronchial, cervical, axillary, and inguinal lymph glands, and of the tonsils. The spleen was frequently somewhat enlarged and on section the Malpighian corpuscles stood up as

raised, pale, transparent nodules, much as they did in typical "sago spleen." The thymus showed changes identical with those in the lymphoid tissue elsewhere. On histological examination one was struck by the resemblance of the lesions found to those described by Mallory in typhoid fever. The reaction was the same throughout the lymphoid tissue regardless of its location. Some of the lymphoid nodules might present a normal appearance, but the majority consisted of a zone of lymphocytes surrounding a more or les sharply circumscribed pale center. High magnification showed the center of the lobule to consist chiefly of large endothelial cells with oval vesicular nuclei. These cells were similar to those lining the lymph sinuses, but most of them were larger and took the stain very lightly. Scattered throughout the center of the nodule were broken down cells and granular fragments of necrotic nuclei, and in areas with extensive necrosis there was often an invasion of polymorphonuclear leucocytes. In the lymph sinuses there were large numbers of the same phagocytic endothelial cells and extensive proliferation of these endothelial cells, which was shown by the frequency with which mitotic figures were found. Necrotic cells were met with in the lymph sinuses, but, in general, necrosis was a more prominent feature in the centers of the lymphatic nodules, and proliferation in the lymph sinuses. Among the parenchymatous organs "cloudy swelling" was usually met with; in the liver, however, it resembled in character what had been described by Mallory in typhoid fever. They were for the most part sharply circumscribed areas of necrosis, ranging in size from lesions which consisted of one or two cells to others which embraced nearly one-eighth of a liver lobule. The character of the lesion varied with its size and age, but in general was very constant. The earlier lesions consisted of one or two disintegrating liver cells, with homogeneous, hyalin, pink-staining protoplasm, and occasionally with irregular, degenerated nuclei. In the older lesions an early and rapid degeneration was more apparent than in the necrotic liver cells. The cells were often arranged circularly, in acini, or in double columns. This arrangement simulated that in normal bile ducts, but it was found in association with lesions near the central and sublobular veins, as well as in the portal spaces. Surrounding the necrotic and regenerating liver cells there was usually a network of hyalin, fibrin-like material, and growing into this were many small capillaries. Scattered throughout the lesion were lymphocytes and frequently many polymorphonuclear leucocytes. That these changes were part of the reaction of the body to the virus poliomyelitis would seem to be made certain by the fact that exactly similar lesions might be found in the organs of monkeys which had been experimentally infected with the disease. The demonstration of such a widespread reaction to the virus and the close resemblance of the histological changes produced to those of typhoid fever were wholly in line with recent clinical and epidemiological advances which tended to recognize acute poliomyelitis as a general infection. The disease must be regarded as a widespread process which affected parenchymatous organs, lymphoid tissue, and, more especially, the nervous system. The demonstration of definite anatomical lesions in organs which had been shown to contain the virus was of considerable importance in helping to complete the picture of a general infection and emphasized the probable importance of the nasopharynx in the epidemiology of the disease.

The Blood and Spinal Fluid in Poliomyelitis.—Dr George Draper made this report. He told of the work that had been done with a twofold object, that of diagnosis and course. The material used was from 233 fluids from 69 cases, and it was taken as follows: 1st week, 43 cases; 2nd week, 45 cases; 3rd week, 40 cases; and 4th week, 30 cases. They investigated the pressure and gross appearance (usually clear, occasionally opaque, and sometimes clotted), the cell count, the chlorides, the reduction by Fehling's, and the globulin. With regard to the pressure, there was possibly in general an increase. The chlorides were normal. The reduction by Fehling's was normal. Early in the disease the polymorphonuclears outnumbered the mononuclears; similar changes had been noted by Flexner and Lewis. Of the 43 cases, 1st week, 23 had over 50 cells and 38 were above the normal, while in two prodromal cases there were 990 and 650 cells per case, respectively. Of the 45 cases, 2nd week, 8 had over 50 cells, and 23 above the normal. Of the 40 cases, 3rd week, there were 1 case over 50 and 8 above normal. The types of fluid presented (1) common, with a normal or slightly increased cell count and with well marked globulin; (2) a high cell count with normal or slight globulin; (3) normal or low cell count with a high gobulin. Each type apparently was characteristic of the stage of the disease, the cellular in the early days of the acute stage, the albuminous in the later stages of the acute stage. With regard to the early diagnosis, the cases examined before the onset of the paralysis were of the greatest interest. Six cases were seen in what might be termed the prodromal period. Of these, four later developed paralysis and two proved to be of the abortive type. The fluid obtained from a lumbar puncture made on the fourth day after the onset in one case gave a cell count of 650 per c.mm., 90 per cent. polynuclears, and a globulin reaction. Three days after the child suddenly developed paralysis and in five hours died of respiratory failure. A second case was seen on the day after the onset of symptoms. The spinal fluid contained 990 cells per c.mm., 90 per cent. of which were polymorphonuclears, and the globulin reaction was positive. On the following day one leg was paralyzed and the cell count of the spinal fluid was 627 per c.mm. with 80 per cent. mononuclears. On the next day both legs were paralyzed and the cell count was 1221 per c.mm. with 92 per cent. mononuclears including many large phagocytic cells. The globulin reaction was positve. Thus two cases seen early in the course of the disease showed fluids with unusually high cell counts, and with a marked predominance of polymorphonuclear cells. In one of them the change of the cell picture from the polymorphonuclear type to the mononuclear could be followed coincident with the onset of the paralysis. Three other cases in the prodromal period, one an abortive case and two becoming paralyzed on the day of the first lumbar puncture, gave cell counts of 37, 94, and 113 per c.mm. with 100 per cent., 93 per cent., and 83 per cent. of mononuclear cells, respectively, and globulin reactions which fell within normal limits. Finally, in one abortive case lumbar puncture on the second day after the onset of symptoms gave a wholly normal fluid. On the third day the cell count was 62 per c.mm. with 89 per cent. mononuclears and a positive globulin reaction. On the sixth day the cell count was 59 per c.mm., all mononuclears, and globulin positive. On the eleventh day the spinal fluid was again normal. That this was an abortive case of poliomyeltitis was proved later by showing that the patient's blood serum was capable of neutralizing active virus when mixed with it and injected intracranially into a monkey. In these six cases examination of the spinal fluid gave evidence which was helpful in making a diagnosis of poliomyelitis before the onset of paralysis. Similar evidence was afforded by eleven cases of Lucas and by one of Frissell. In none of these cases was a large percentage of polymorphonuclear cells found, but it seemed important to call attention to the fact that a fluid whose cytology resembled that found in cerebrospinal meningitis and other types of purulent meningitis might also occur in the early stages of poliomyelitis.

Dr. Edward D. Fisher said that in poliomyelitis there

was a general infection of all of the organs of the body, but this particular lesion was, as shown by the pathological findings, localized chiefly in the spinal cord substance itself. Meningitis manifested itself only to a minor degree. The value of the work in the laboratory was very great if the workers there kept in touch with the clinicians. The object of present investigation should be the study of prevention of the disease, that could be carried out in the laboratory, but the treatment of poliomyelitis, Dr. Fisher said, would always remain in the hands of the trained clinician.

Dr. S. J. Meltzer asked Dr. Peabody whether he did not think the observed visceral changes in poliomyelitis which concerned essentially the lymphoid tissues could be only secondary results, reactions to the products of the primary inflammation which were perhaps indeed confined to the central nervous system. Regarding the remark of Dr. Draper that the study of the spinal fluid did not seem to furnish any definite results which were of diagnostic value, Dr. Meltzer referred to his recent discovery that spinal fluid was capable of destroying added adrenalin, and that the destructive action of the spinal fluid from cases of poliomyelitis was definitely more marked than that of the spinal fluid from tuberculous meningitis, a point which could be elaborated to a differential diagnosis between these two diseases.

The Treatment of Syphilis of the Nervous System.—Dr. H. F. Swift and Dr. A. W. M. Ellis presented this communication. They said the central nervous system was frequently involved in syphilis, not only in the late stages, but early. This was explained by the early, general distribution of the spirochete. Although the spirochetes were found in the blood at times, they were specially adapted to the lymph spaces. The subaraehnoid space could be considered the great lymph sheath of the central nervous system. This probably explained the frequent involvement of the brain. Because of the peculiar pathological conditions existing in the vessels of the central nervous system it was difficult to have the curative agent completely supplied by the blood stream. There was considerable evidence that the blood serum of patients treated with salvarsan had a curative action on syphilitic lesions. In a number of cases this serum had been applied directly to the central nervous system by means of injection after lumbar puncture. Charts were shown of several patients in whom there was a decidedly beneficial effect from this form of treatment. In one the treatment was by direct application of the serum alone; in the others by combined intravenous injections of salvarsan and injections of serum into the spinal canal. The announcement was only preliminary, but seemed to promise favorable results, especially in the more resistant cases.

Dr. Joseph Collins said that he was gratified to see that the internist and the syphilologist had come to believe what the neurologist had been shouting from the house tops for many years, namely, that syphilis of the nervous system was not necessarily a late manifestation of syphilis, or what was colloquially called a manifestation of tertiary syphilis; but that frequently a tissue was affected soon after the original infection. Now that the internist had come to the propaganda of this teaching it might be accepted, just as was psychotheraphy when they began to talk about it. Dr. Swift's paper was of interest to him for several reasons. First, because of the statement that salvarsan or other medicament administered internally could not be recovered from the spinal fluid and that, therefore, it occurred to him to inject a certain quantity of serum taken from the blood of an individual who had just previously been given salvarsan. Secondly, because of the very small quantity of serum that Dr. Swift had been content to use. Thirdly, because the results which Dr. Swift obtained and reported did not compare favorably with those which Dr. Armour and Dr. Collins had obtained in a long series of cases of organic nervous diseases, and which they were about to publish. In the plan of treatment proposed by Dr. Swift the amount of salvarsan that was introduced into the spinal canal must be extremely small, keeping in mind the dose that was given first intravenously and the small amount of serum that was introduced into the spinal canal. One naturally was led to ask if it was the salvarsan in the serum that acted or whether it was not the result of some unusual immunity reaction involving the formation of soluble principles or antibodies in the spinal fluid. Dr. Collins said that if they were going to discuss the beneficial effects of salvarsan upon spinal cord diseases, such as tabes, they must differentiate between cases that presented the classical features of tabes but whose spinal fluid showed a low leucocyte count, for instance below 40 cells to the cubic millimeter, and those which presented similarly convincing so-called pathognomonic signs but whose spinal fluid showed a very large cell count, oftentimes many hundreds to the cubic millimeter, for it was in the latter type of cases that they might most confidently expect beneficial results from salvarsan therapy. Dr. Collins concluded by saying that he did not consider this to be an opportune time to discuss the pathogenesis of tabes, but surely a study of the cases to which salvarsan had been administered, *i.e.* cases in which careful study had been made of the cerebrospinal fluid before and after treatment, tended to bear out the view that they were dealing primarily with a meningitis and a secondary root-neuritis.

Dr. John A. Fordyce was glad that Dr. Swift had emphasized the occurrence of early involvement of the nervous system in syphilis. He had found that the general practitioner believed the nervous system was involved chiefly late in the disease, and while this was often true in tabes and paresis it was not uncommon to see forms of cerebral and cerebrospinal syphilis in the first year of the infection. He called attention to a case of very intense meningitis of the brain which had occurred three months after an initial lesion of the upper lip with a fatal termination. He also recalled a case of cerebrospinal syphilis coming on six months after infection, in which complete recovery took place after prolonged and intensive treatment. A renewed interest had been taken in the early infection of the nervous system in syphilis within the past year or two, or since salvarsan had been used so extensively in this disease; the claim having been made that these so-called nerve recurrences were due to the drug and not to the underlying disease. It had been, however, pretty conclusively demonstrated that such affections were due to incomplete treatment of the patient and not to the drug. He also called attention to the fact that certain syphilitic lesions of the skin and mucous membranes responded promptly to treatment, while others yielded with extreme slowness. This was especially true of certain forms of interstitial glossitis and leucoplakias of the tongue and mouth and scaling syphilides of the palm. The employment of intensive treatment over a long period of time was required to bring about a resolution of these forms of the disease. He believed that an analogy could be drawn between some of these obstinate skin and mucous membrane lesions of the disease and certain resistant forms of syphilis of the nervous system.

Dr. S. J. Meltzer remarked that Dr. Swift's interesting observation ought to be controlled by an intraspinal injection of serum from a case which was not yet treated, or simply from a normal individual; it was conceivable that the injection of normal serum into the spinal canal was capable of relieving the tabetic pains.

Rhythmic Changes in the Human Heart.—Dr. Canby Robinson showed on the screen some tracings that he had recently made.

Stated Meeting, Held February 1, 1912.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

National Quarantine.—DR. WILLIAM M. POLK, in his opening remarks referred to the duty of the president to have presented at each of the Academy's meetings some subject bearing upon the science and art of medicine. One of the greatest departments in medicine was "preventive medicine," and this was intimately connected with quarantine, especially as it was administered in connection with maritime commerce and with immigration. A fruitful source of disease existed in each of these activities and each equipped itself with a clinical and laboratory staff in order that difficulties pertaining to medical inspection and supervision might be met at the ports of entry. When one reflected that after entering some of these disorders had a tendency to spread rapidly, a reason for interest in quarantine was evident. Moreover, when it was realized that while the people at large were the chief sufferers, the members of the Academy, in common with all the physicians of the city, must bear the brunt of such evil situations as faulty quarantine was apt to encourage; therefore, their interest could be regarded as no more than natural. In fact, they had a duty right there, and this duty was "inquiry." New York was one of the four ports within the United States outside National Quarantine. When one learned of the urgent need for sanitation in towns and communities dependent upon the State Board of Health and how inadequate was the sum allowed for this work, one was tempted to ask why not divert this expenditure into a channel where it was needed far more. It should be understood, however, that even now State Quarantine was dependent upon the National Quarantine. For all the information gathered at foreign ports and all precautions taken outside this port against infectious diseases, we were indebted to the National Quarantine. Already a large part of the quarantine work of this port was done by the National Department of Commerce and Labor. It would be a simple step to place the nation in charge of all the quarantine at this port, and it would be for the good of this community and the betterment of the health conditions throughout the State at large.

Advantages of National Control of Quarantine.—DR. LELAND E. COFER, Assistant Surgeon-General, United States Public Health and Marine Hospital Service, said he would endeavor to explain the national system of quarantine and the advantages which he believed were peculiar to it. Quarantine might be defined as an institution which prevented or modified the transmission of disease from one locality to another by the imposition of certain restrictions upon commercial intercourse. While quarantine was an offspring of medical science, it only throve when communities allowed themselves to be infected by quarantinable diseases, and its operations were unfortunately not then directed against the community so infected, but rather against the social and commercial intercourse between them. This was unfortunate and caused quarantine to be considered of such a palliative nature that progressive sanitarians were ever looking forward to the time when internal sanitary conditions would be developed to such an extent that medical science would be warranted in dropping quarantine as an obsolete and unnecessary measure. Fortunately sanitation was keeping pace with the other sciences in the march of progress. Prior to the passage of the act (approved February 15, 1893) "granting additional quarantine powers and imposing additional duties upon the Marine Hospital Service," there was no national system of quarantine. Prior to 1893 the various State governments conducted their own quarantine systems. If the system had not been faulty and a burden upon commerce, not nearly so many States would have transferred their quarantine functions to the custody of the national government. In the act of 1893 the Secretary of the Treasury was empowered to promulgate uniform quarantine regulations for the ports of the United States, to be enforced by the State or municipal authorities, provided they would undertake to enforce them. In the event that they refused or failed to enforce these regulations, the President was directed to detail or appoint officers for this purpose. At a large number of ports the quarantine had been given over voluntarily to the national government, which exacted no fees; at other ports the national government had assumed charge by virtue of the law and because of noncompliance with the regulations. The quarantine functions at all of the ports of the Atlantic, Pacific, and Gulf seaboards were being operated under national control by the Department of the Treasury, under the Bureau of Public Health and Marine Hospital Service, with the following exceptions: Port of New York, Port of Buffalo, Port of Baltimore, Port of Providence, R. I. Dr. Cofer then gave a brief outline of the manner in which the national quarantine was conducted. In enumerating the factors which they had by a long process of education instilled into their officers for their consideration in determining the sanitary status of a vessel, he offered the following: (1) The facts concerning the sanitary status of the port of departure, which were obtainable from the bills of health, the ship's papers, the public health reports, and special information sent from the Bureau of Public Health and Marine Hospital Service. (2) The facts gathered from the personal observation on the part of the quarantine officer of the ship and its personnel. (3) Suppositions based upon (a) the sanitary history of the voyage; (b) the likelihood of latent infection; (c) the reputation of the captain of the ship; (d) the likelihood of concealed infection; (e) the attitude of the ship's surgeon; (f) the kind of cargo carried. By latent infection he meant the presence on board the vessel of plague-infected rats, or, perhaps, infected yellow-fever mosquitos, which vermin and insects, as the case might be, had not, up to the time of arrival, caused the infection of any of the personnel of the vessel. The Public Health and Marine Hospital Service was under the supervision of the Secretary of the Treasury, and was in charge of the Surgeon-General, who had six Assistant Surgeon-Generals in charge of the Bureau divisions. These divisions were as follows: (1) Foreign and Insular Quarantine and Immigration. (2) Domestic (Interstate) Quarantine. (3) Personnel and Accounts. (4) Marine Hospital and Relief. (5) Scientific Research and Sanitation. (6) Sanitary Reports and Statistics. Each division had special office quarters and a special clerical force. Through the division of Foreign and Insular Quarantine and Immigration, during the fiscal year just past, 15,160 vessels were inspected, involving the inspection of 1,516,445 persons, and the disinfection of 1,801 vessels on account of actual infection or for the destruction of rats and mosquitos, the carriers of plague and yellow fever. This division also supervised the medical inspection of immigrants and during the year ending June 30, 1911, 1,093,008 immigrants were inspected and 14,736 immigrants were rejected on account of diseases deportable under the immigration laws. The Public Health and Marine Hospital Service was composed of 135 commissioned officers, 283 acting assistant surgeons and 1,014 men. Representatives of this corps would be found in marine hospitals or in immigration or quarantine stations in every port and in the important cities and towns bordering upon the Canadian and Mexican frontiers. The service at the present time operated 46 quarantine stations extending along the Pacific, Gulf, and Atlantic seaboards from Alaska to Maine, and also the quarantine systems in the Philippines, Hawaii and Porto Rico. The diseases at present quarantined against under national law were cholera, yellow fever, smallpox, typhus fever, leprosy, and plague.

National Quarantine.—Hon. William Williams, Commissioner of Immigration, Port of New York, said that quarantine questions had, at various times, engaged the attention of the courts. This interesting extract from an opinion of the Supreme Court in the case of Morgan S.S. Co. *vs.* Louisiana Board of Health, 118 U. S. 455, was worth noting: "For the period of nearly a century since the government was organized Congress has passed no quarantine law, nor any other law to protect the inhabitants of the United States against the invasion of contagious and infectious diseases from abroad; and yet during the early part of the present century for many years the cities of the Atlantic Coast from Boston and New York to Charleston were devastated by yellow fever. In later times the cholera had made similar invasions; and the yellow fever had been unchecked in its fearful course in the Southern cities, New Orleans especially, for several generations. During all this time the Congress of the United States never attempted to exercise this or any other power to protect the people from the ravages of these dreadful diseases. No doubt they believed that the power to do this belonged to the States." In the course of the opinion the Court further said: "Whenever Congress shall undertake to provide for the commercial cities of the United States a general system of quarantine—*all State laws on the subject shall be abrogated*, at least so far as the two are inconsistent. But until this is done the laws of the State on the subject are valid." The relations of the State and Federal governments as regards quarantine matters were somewhat similar to those prevailing in bankruptcy matters. Recently the Federal government enacted a bankruptcy law which superseded all State laws. The question whether quarantine should be managed by the Federal or State government seemed to him to be a one-sided one. He had yet to hear a valid argument advanced why in New York, as almost everywhere else in the United States, it should not be in the hands of the Federal government. The question had an administrative and a medical side. Any remarks of his presupposed that the State could and would do the *medical* work as well as the Federal government. But it was in the interest of good administration that it be done by he Federal government because it dealt with matters national in character. This was shown in many ways. International conventions existed concerning quarantine matters. Indeed, without the best cooperation of other governments the best results could not be obtained. Furthermore, the whole country, not simply New York State, was interested in the execution of quarantine regulations at our port. To refer only to the immigrants that came through it, of some 830,000 who arrived in 1910, more than two-thirds went to places outside of New York State. And since the question was national in character, there was incidentally no reason why citizens of the State of New York should bear the financial burdens of a quarantine which served the whole country. The Federal government already carried on an enormous amount of medical work. Some of its medical agencies outside of the War and Navy Departments included the Public Health and Marine Hospital Service, the medical officers of the Revenue Cutter Service, Pension Office, the Indian Bureau and Old Soldiers' Homes, the Government Hospital for the Insane, and the Bureaus of Entomology and Chemistry. Not only did it conduct the quarantine work at all but three or four ports of the United States, but even at those ports where the State had charge of this work the Federal government must, under existing statutes, supervise its performance and intervene where it was unsatisfactorily done. This duty of supervising might readily result in friction. Besides incidentally the regulations of Boston and New York (both under State control) might differ, and different supervision be required at the two places. Congress was now considering the union in one bureau or department of all government medical agencies outside of the War and Navy Departments, and it would seem as a proper preliminary to this that it should gather in all quarantine stations. Mr. Williams mentioned some other matters to show to what extent the government was already in this business. It sent its surgeons abroad to study and report on health conditions. Then there was the "Passenger Act," an important measure about which very few people knew, requiring certain sanitary arrangements to be maintained on board ships both American and foreign, and proper food to be supplied. Its provisions hung very closely together with and were intended to facilitate the execution of the quarantine regulations. Lastly they came to Ellis Island. There they had a very substantial medical establishment. The surgeons, nurses, and attendants numbered over 100, and the hospitals were of fine modern design and equipment. A vast amount of medical work was done there, for they inspected all immigrants, sometimes a million a year, with reference to every physical and mental defect not covered by the quarantine laws. Ellis Island was a second line of defense, and any quarantinable disease which might escape the notice of the quarantine authorities would be held by their surgeons. Included in the diseases which operated to exclude immigrants were all of a dangerous contagious or loathsome character. In one respect the work of the quarantine and immigration officers overlapped. Two years ago the health and immigration authorities of New York agreed that good administration called for the removal at quarantine of patients suffering from such acute infectious diseases as measles, scarlet fever, and diphtheria. But a number of measles cases broke out between the time immigrants left quarantine and reached Ellis Island, and such cases were now cared for by the Federal government in its own hospitals. He closed by saying that the Federal government should perform those functions of government which were national in character and from every point of view the business of managing quarantine at the great port of New York was national in character.

Dr. Geo. W. Stoner, Surgeon Public Health and Marine Hospital Service, Chief Medical Officer, Ellis Island, New York, said that Dr. Cofer's statement regarding the supplemental quarantine work performed by medical officers of the Public Health and Marine Hospital Service engaged in the medical examination of arriving aliens and the advantage thus afforded to the maritime interests and the quarantine functions of a port, and of necessity the public at large, applied not only to the few ports—New York, Boston, and Baltimore, where maritime quarantine was still under State or municipal control, but to all the ports in the United States. If any quarantinable disease broke out, or any signs or symptoms of such disease were observed among the passengers or crew, after the ship passed quarantine at the entrance of the harbor and before the medical examination at the inner harbor (the Immigration Station) was completed, it was the bounden duty of the immigration medical examiner (the Public Health and Marine Hospital Service Officer) immediately to communicate the facts to the quarantine officer and at the same time perform or assist in the performance of all the quarantine functions pertaining to the case in such emergency—remove the sick, isolate the suspects, segregate the exposed, or, as would more likely be the case, remand the ship and all on board to quarantine again. The successful outcome in such emergency must, of necessity, depend upon the efficiency of the second (the Immigration medical) examination. But he believed that they would all agree that even the highest degree of efficiency might not avail in the absence of harmonious relations between the two stations; and as Dr. Cofer indicated, such relations were doubly secured at ports where the quarantine and the immigration work was conducted by officers of the same service who for the most part had had uniform training

and experience in quarantine as well as in immigration work. The necessary qualification of a quarantine officer was a thorough practical knowledge of quarantine, which meant everything pertaining to the best methods of preventing the introduction and the spread of contagious quarantinable diseases—cholera, yellow fever, smallpox, typhus fever, leprosy, and plague. All other diseases or defects, mental or physical were, so to speak, outside the province of the quarantine officer. Under certain conditions, however, he might be called upon, or feel in duty bound, to exercise the quarantine function and extend the same so as to include the acute contagious diseases, such as measles, scarlet fever, etc., not classified as maritime quarantinable—as was the case last year and year before here at the Port of New York, when the City Health Department Hospitals, where for years and years immigrants suffering from such diseases had been received and cared for (at so much per diem, of course, chargeable to the government but reimbursed by the steamship companies), declined, or were unable, to continue the care of these patients, and this at a time, too, when the new hospital buildings at Ellis Island were not yet ready for the reception of persons suffering from such diseases. At this juncture the Quarantine Officer agreed to receive from the Commissioner of Immigration and care for at the quarantine hospitals all cases of measles, scarlet fever, etc., occurring among arriving aliens. Many were removed directly from the ships at quarantine and a considerable number were sent down from Ellis Island. But in June last the new hospital at Ellis Island was put in commission and now all sick arriving aliens are being cared for there, except such as may be afflicted with the maritime quarantinable diseases above referred to.

The PRESIDENT announced that the recommendations contained in the papers would be referred to the Council of the Academy for consideration and with the request that they report back to the Academy. This was put in the form of a motion, was seconded, and unanimously carried

Dr. WILLIAM T. JENKINS said that he regarded the State fully able to maintain an effective quarantine at the Port of New York. He said he was health officer of the Port in 1892 and 1893 before the Public Health branch of the Marine Hospital Service was established. He combated an outbreak of typhus fever without Federal aid and was successful in preventing the entrance of cholera. When rumors of the prevalence of cholera in Hamburg were heard, he sent a representative abroad to report on the situation and was kept advised regarding the sailing of infected ships. He did not want the New York quarantine transferred from State to Federal control.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 13, 1911.

Dr. WILLIAM SHANNON IN THE CHAIR.

Outdoor Sleeping Devices in Cities.—Dr. S. ADOLPHUS KNOPF read this paper and demonstrated the devices he described. In order to make the open-air treatment of tuberculosis, pneumonia, or nervous diseases feasible, even in the homes of the poor in cities, Dr. Knopf had devised a window tent which was attached to the inside instead of the outside of the window. It was so constructed that the air of the room could not enter or mix with the air in the tent. The tent was attached to the frame of the window, but did not entirely fill the lower half, a space of about three inches being left for the escape of the warm air in the room. This space could be reduced to one inch or less. The tent was constructed of a series of frames, made of Bessemer rod suitably formed, furnished with hinged terminals, and covered with extra thick yacht sail twill, properly fitted and having elongated ends which admitted of their being tucked in under and around the bedding to prevent the cold air from entering the room. Shutters or Venetian blinds could be utilized in conjunction with the window tent as a screen to intercept the gaze of neighbors. In stormy weather they were a protection as well. A piece of transparent celluloid was placed in the front of the tent to serve as an observation window for the nurse to watch the patient, if this was necessary. During the day the window tent could be pulled up and the window closed if desired. This window tent was of the greatest service to the tuberculous patient, for he could take his open-air treatment even in the cramped quarters of a city tenement without causing the remainder of the family to suffer from the cold. The patient should, of course, have an abundance of clothing; he should wear a sweater and protect his head and ears with a woolen cap. He then described a device, called the starnook, which was suitable for a rest in the open air by day and for outdoor sleeping by night. He had used one himself since October, 1910. The starnook consisted of three walls composed of frames holding movable slats, of a roof and a floor. It was all made of galvanized iron except the floor, the window sash, and the roof-frame. The wall of the house enclosed the fourth side through which access was had to the starnook. It was about nine feet long by six feet deep by six feet high at the outer side and eight feet high at the inner side. The roof could be completely raised against the walls of the house and an unobscured view of the sky could thus be had. Three upper sections of the front shutters could be entirely opened, making a typical rest-cure veranda during the day. The slats were so constructed as to secure absolute privacy, and in stormy weather could be tightly closed. Even when so closed there were enough open spaces to allow the freest circulation of air. Many conveniences could be added to this arrangement, such as electric light, electric motor contrivances for manipulating the various sections of slats, etc. For those who could not have this convenience a large beach chair could be fitted so as to protect the patient from the winds and render him very comfortable, even admitting of his having a table for books, writing materials, and meals. Dr. Knopf also described the half-tent, which was very light and easily shifted from place to place.

A Demonstration of a New Method of Securing Pure Air in Tenements.—Mr. HENRY ATTERBURY SMITH made this demonstration and stated that this new method of building staircases had been brought about through suggestions made by doctors. Charts were exhibited showing the Vanderbilt tenements on Seventy-seventh Street and East River. These buildings were nearly complete and a similar group of model tenements had been erected in a congested district of Hoboken. The Charity Organization Society had offered a prize ten years ago for any one who could bring about a law that would call for an open passageway and other conditions which would provide fresh air all the time. Mr. Smith presented pictures showing what had been accomplished. The entrances into these tenements were in a court and were one hundred feet apart. They were so arranged as not to be open to abuse or to conditions of immorality. In case of fire one hose could send water from one staircase to ninety-six doors. The shaft was the disagreeable feature about the tenement and should be abolished.

Resolution for Procuring Fresh Air in Tenements.—Dr. A. JACOBI offered the following resolution, which was unanimously carried: "*Whereas*, in the tenement house building laws of the City of New York there is no recognition of the new open-air stairway, doing away with dark halls, and *Whereas*, the airshaft is demanded because of presumed interior dark halls, and *Whereas*, the airshaft becomes superfluous in open-air stairway construction of tenements, as illustrated by the tenements now under con-

struction, Seventy-seventh Street and East River, and *Whereas,* the airshaft, besides being superfluous for purposes of ventilation, takes from the living quarters needed room space, is furthermore a possible means of close communication between adjacent compartments, transmitting noise and possibly dust and germs. Therefore, be it *Resolved* that it be recorded as the sense of this meeting that the airshafts in these new, specially constructed tenements with open-air stairways and without dark inner halls, are superfluous; and be it further *Resolved*, that the Section on Pediatrics recommend that the Building and Tenement House Departments of the City of New York be requested to formulate and secure such laws as shall allow the abolition of the airshafts in such specially constructed tenements and the space now occupied by them be incorporated in the adjoining living rooms; and be it further *Resolved:* That a copy of these resolutions, after endorsement by the Council of the New York Academy of Medicine, be forwarded to the departments regulating the building of tenements."

Dr. HERMANN M. BIGGS said that he had not visited these new tenements, but that Mr. Smith had submitted the plans to the Superintendent of Construction, Department of Health. Formerly the construction of tenements and the plumbing were under the supervision of the Department of Health. It was the opinion of everyone that these airshafts were unnecessary; in fact, that they were a distinct detriment to the houses so constructed.

Remedial Agents of Value in the Treatment of Pneumonia in Children.—Dr. W. P. NORTHRUP read this paper, which he stated had been written for the purpose of provoking discussion and not as an encyclopedic article. In sustaining the heart and vessels to keep the blood-pressure up to the efficient degree for the seven to twelve days' strain he considered the open cold air most valuable. Clinically it had been proved that this was true. Experimentally the explanation of this efficiency had been demonstrated by Howland and Hooker. The proper performance of all functions of the body, glands, muscles, and all tissues had to be backed by a certain blood pressure. Patients slept, retained a clear, bright color, took food, breathed freer, passed the crisis in better form, and entered convalescence in better condition by having been continuously in the cold, bracing, winter out-door-air. Dr. Northrup did not think otitis media was any more frequent in patients inhaling the cold air in the open than among others. He was sure that otitis was more common in institution groups of bronchitic pneumonia patients than in sporadic cases in households. He thought nothing was so bad for a bronchitic pneumonia case as a warm middle room or a crowded warm ward. No matter what one did with a single case he was liable to be sorry. One case proved nothing, but ten, twenty, or thirty years of experience was a basis of conviction. He wished to put the question, "What do experts say in regard to putting in the open air pneumonia, scarlet fever, diphtheria, influenza, pertussis, laryngitis, and otitia media?" Such a discussion might aid many a practitioner to omit some time-honored, annoying, and useless treatment and to substitute a modern helpful one. Dr. Northrup no longer used the pneumonia jacket and rarely used the poultice except for pain. Abdominal distention was one of the most distressing features of pneumonia. He had found an injection of milk and molasses, three ounces of each, was most effective in relieving this symptom. He also recommended hot high saline injections and turpentine in emulsion by injection. In considering pneumonia with tendency to heart failure, the writer said that this might mean different things to different people. When a patient's color changed so that a nurse noticed it, either to a leaden or to a pale color with a tinge of cyanosis and the heart became rapid, that heart was dangerously bad. Early in the disease the toxins acted like an alkaloid tonic or stimulant. At the end of a week it might be that the need of a stimulant became apparent. Even a little before this the stimulant should be begun. He recommended the use of digitalis first, tincture or fluid extract, later strophanthus, alternating dose and dose. After this strychnine and whiskey. The best heart tonic was cold, open, fresh air. The best first emergency stimulant was a hot foot bath; the second, a hot saline and whiskey bowel injection; the third, was a hypodermic injection of camphor, caffeine, adrenalin, or glonoin. The treatment of pneumonia had entirely changed recently, and Dr. Northrup hoped that the discussion would show where the profession now stood.

Dr. HERMANN M. BIGGS said that he felt out of place in undertaking a discussion on the treatment of pneumonia in children and that he would refer to only one phase of the subject. He thought they were under great obligations to Dr. Northrup for the emphasis he had placed on the treatment of affections of the respiratory tract and other affections of children by the open-air methods. In the Health Department they had come to believe more and more in the treatment of the diseases with which they were called upon to deal with in open air. At Otisville, where they had established a sanatorium for the tuberculous, they had learned that they could take patients from the tenements, place them out-doors, and while they might suffer somewhat from the intense cold, there was no distinct detriment to their condition. The results were always favorable, and at the end of a week or ten days they became accustomed to the open-air life and it was not at all objectionable. Sometimes three or four inches of snow would fall on the beds on which they slept. Since this institution had been opened, five years ago, there had never been a single instance of any severe acute affection of the respiratory tract as the result of exposure to fresh air and the cold Four years ago when the mortality at the Kingston Avenue Hospital, in Brooklyn, was so high, probably caused in part by the crowded wards, the Board of Health decided to build some temporary shacks and to place in these the patients afflicted with bronchopneumonia, keeping them in the open air as much as possible. The results were most gratifying. They found that the patients having severe bronchopneumonia and the septic complications of measles, when taken from the wards and placed in the fresh air did much better. Many of them went into convalescence without any serious trouble after removal from the wards of the hospital. Now there were in course of construction two pavilions which would contain 160 beds at the Riverside Hospital, and these would be used for contagious diseases and pulmonary tuberculosis. In East Sixteenth Street there were 320 beds and one side of the ward was as open as it could be made. Dr. Biggs believed that this method of treating contagious diseases as well as all forms of infection was the one they must follow in the future. Dr. Biggs had visited Dr. Northrup's wards at the Presbyterian Hospital, and notwithstanding the exposure to the open air, the patients showed that only favorable results followed. He said he believed that in a well-ventilated room infections could not be carried far. He had visited many of the hospitals for contagious diseases in Europe and was impressed with the fact that they did not separate the various forms of infection as they did in this country. In Paris, where the infectious diseases were cared for, all forms were looked after in the same pavilion, but with glass boxes eight by ten feet that opened into a corridor. In accordance with the suggestions obtained patients were now being separated by glass and wood partitions. At most there were only two beds to a stall.

Dr. CHARLES GILMORE KERLEY said that in assuming the care of any child afflicted with pneumonia there were many things which should be taken into consideration

The child's condition was temporarily changed; there existed something which depressed the child's vitality to the utmost and, therefore, all the little details of life should be attended to. A child with fever had a lessened digestive capacity and if the food usually taken was continued there would result in many cases intestinal toxemia and a ballooning of the abdomen. Some laxative should be administered, preferably castor oil. The diet should be reduced. Fat milk should not be given. The food should be reduced in amount at least one-half or two-thirds so as to avoid the toxemia and the distention of the abdomen which caused compression upon the diaphragm. The ordinary clothing should be worn, and not the oiled silk or other jackets which made the child so uncomfortable. The child should be kept as quiet as possible; he was very susceptible to nervous influences when well and much more so when ill. He should get food and rest at stated intervals. Only one person should be allowed in the sick room at a time. The child should not be fussed over and it would be better to keep members of the family from the room. To make the child comfortable often a Dover's powder or a cold compress might be required. With regard to fresh air, Dr. Kerley said he was not yet willing to place patients with true laryngeal inflammations on the roof and in the open; these cases did not do well in the cold air. The element of spasm should be borne in mind and this was increased when the child was exposed to the cold. In bronchial asthma the cold air might make the respirations more rapid; if the air was fresh, but not cold, the breathing was more easy. Exposing the child with bronchial asthma to the extreme cold he did not believe in. If one placed a child in quiet quarters, with proper feeding, with plenty of good and fresh air, with freedom from overtension, one had done all that was necessary for his good in many cases. If, however, the child was very sick something must be done in the line of drugs. The giving of expectorants, syrup of ipecac, of tulu, and other such stuffs certainly tended to upset the child's digestion, diminished his capacity for taking food, and took from him a certain amount of energy. Whatever food was ordered should be selected so as not to compromise the child's digestive capacity. There were many cases that required cardiac stimulation because of bad management; some children were in a toxic state from causes not due to the disease itself. When stimulants were required they should be given by the hypodermic method, because the stomach could not be relied upon. With a pulse of low tension and irregular, Dr. Kerley said he knew of no better agent than strychnine. He did not like to use digitalis because it tended to upset the stomach. Alcohol should be held in reserve until the seventh, eighth, or ninth day of the disease and then given only when other medication failed; when given it should be in large doses. It was surprising how much alcohol these patients could take and retain and without any signs of intoxication. He cautioned against the administration of alcohol early in the disease; give it late in the disease if at all. It was an agent to hold in reserve. Hydrotherapy, the cold pack, or the modified pack, were means of improving the heart's condition.

Dr. Rowland G. Freeman said that the old belief that measles was to be treated in the dark because of danger to the eyes had no ground at all; the eyes of patients with measles did as well in the light as in the dark. The bright sunlight did not harm the eyes of patients with measles any more than it would if they did not have the disease. A patient with measles should be placed near the open window, but the direct rays of the sun should not fall on the patient's eyes. Draughts were not to be feared. There should be plenty of sunlight and fresh air, things that were very difficult often to provide in many families. The results of this treatment were often surprising. The low mortality rate in many institutions was due largely to the fresh air. One should endeavor always to have open windows, sunlight, and fresh air; wonderful results often followed this treatment. With regard to measles-pneumonia, when the disease first appeared calomel should first be administered, and a mustard paste applied to the chest. Plenty of fresh air and sunlight should be allowed. The patient should be kept quiet. Fresh air did as much good as steam inhalations. A bronchitis was not a contraindication at all. In cases with a moist skin exposure to the open air would soon cause the skin to become dry.

Dr. B. Raymond Hoobler said that through the courtesy of Dr. Howland he had had the opportunity of observing the blood pressure on several hundred children in his wards at Bellevue Hospital. The observations had been on children with various diseases and in various stages of such diseases, taken indoors and after being in the open air. The findings which he reported applied only to lobar and bronchopneumonia, but were applicable to nearly all forms of acute respiratory conditions. The children when they were placed in the open air were properly protected with warm clothing, only their faces being exposed. The results might briefly be stated as follows: As a general rule the blood pressure was increased when a child was removed from a warm ward to the open air. The amount of such a rise was dependent upon several factors: (1) The more sick the child, the higher was the rise of pressure. (2) The higher the patient's temperature, the higher the rise of pressure. (3) The warmer the indoor temperature and the colder the outdoor temperature, the greater would be the rise. (4) The lower the blood pressure before placing the child in the cold air the higher would be the rise. (5) The blood pressure remained high as long as the child was left in the open air. (6) Drugs which had the effect of raising the blood pressure indoors 15 mm. of mercury would have but little effect if given when the patient was outdoors after the maximum effect of the cold had been reached. (7) The maximum effect of cold air was reached after about two hours in the open air. (8) Blood pressure fell gradually when the patient was brought indoors and reached its minimum after about two hours. (9) There was no dropping in the blood pressure below the usual indoor pressure as was the case with many vasomotor stimulants when the patient was brought in from outdoors. (10) Infants did not respond as well as did the older children. (11) The pulse and temperature would remain about the same, the only difference being in the blood pressure which accounted for the value of the outdoor treatment.

Dr. A. Jacobi said that Dickson in 1836 wrote a book on the mortality and morbidity of pneumonia in children and he stated that at that time of thirty-five patients only one remained alive; to-day, out of the same number it was found that only one died. The difference in the mortality was, of course, due to the different methods of treatment. When Dr. Jacobi entered into the practice of medicine it was the custom to keep the rooms warm, the windows closed. Water was not given the sick, but warm teas were. The children were kept warm and covered; in fact, they were not ever uncovered. This was sixty years ago. Fat milk should not be given in any acute infectious disease; the carbohydrates were the proper food to give. Many cases of pneumonia got along without any treatment, but it had always been a question with Dr. Jacobi whether getting well without treatment with drugs meant that these patients really did get well. When a patient, ill with an acute infectious disease, suffered from symptoms which lasted ten, eight, or even five days, with a high temperature that remained unchecked for such a length of time, it was a mistake to believe in no treatment. High temperatures in these diseases injured the patient's vitality—injured the myocardium. It was his practice not

to wait until things turned up; he did not believe in "Micawberism." Pay some attention to the heart. Give digitalis in the beginning of the disease, or strophanthus, or both together. Babies who were wakeful should not receive caffeine. He believed in giving opiates to children; as good results were obtained in children as in adults. The best stimulant, however, was camphor, given hypodermically, one part of camphor to four parts of sweet almond oil (not olive oil). In cases of pneumonia which did not readily undergo resolution, with thickened expectoration, etc., inhalations did well, especially with turpentine. The crude turpentine obtained from paint shops was what should be used. He had also used with success inhalations of chloride of ammonia; this salt was burned on a living coal or placed in a hot over or stove. It aided very much in expectoration and was well worth trying.

Dr. HENRY KOPLIK said that the tendency in pneumonia, as in typhoid fever, was to get well. The mortality in pneumonia differed according to the age of the patients; above the age of five the disease was quite benign. In different epidemics the disease gave different reactions. It should be borne in mind that pneumonia in children had a tendency towards recovery; but they also had a tendency to spread to both lungs, and many such patients died. Good results were obtained by placing children where they could get plenty of fresh air and good ventilation.

Dr. JACOBI said that the giving of digitalis by the drop method was absolutely useless. He used this agent very rarely. If he was dealing with a chronic case, however, knowing the heart muscle was in uniformly good condition, he might use it. One should remember that strychnine might overstimulate a weak portion of the heart and cause trouble. In cases of chronic endocarditis, strychnine should never be used. He seldom used it in small children. This was a drug that was used too much. In Europe it was not used to the extent that it was in the United States.

SECTION ON SURGERY.

Stated Meeting, Held, March 3, 1911.

DR. GEORGE WOOLSEY IN THE CHAIR.

Streptococcic Infection of the Knee Joint.—Dr. WALTER C. CRAMP presented this patient. In December, 1910, a boy 12 years of age was struck by a pair of iron pliers which inflicted a penetrating wound of the right knee. Five days later he was admitted to Bellevue Hospital with a temperature of 103.8° F. The joint was distended with pus. Incisions were made on either side of the patella and also laterally and posteriorly; to drain lateral pouches of the joint rubber tube drainage was instituted. The patient was treated with 1 to 10,000 bichloride solution for ten days. They began to remove the drains on the twelfth day and all were out on the sixteenth day. The patient was up and walking without crutches in the fifth week. At present, two and one-half months after the injury, the patient had 90 degrees flexion, no pain and walked with only a slight limp. Culture proved that the pus evacuated from the wound was streptococcus.

Chronic Glanders in Man—Report of a Case Treated with Glanders Vaccine.—Dr. WALTER C. CRAMP reported this case. He stated that a review of the study of C. D. Robin of the Royal Victoria Hospital, Canada, of 156 cases of chronic glanders collected from medical literature had led to the conclusion that chronic glanders in man was an exceedingly rare disease and that the mortality was extremely high, only 6 per cent. of the 156 cases being positively known to have been cured. Dr. Cramp's patient was a Pole, 34 years of age, a cement worker, who was admitted to Bellevue on October 20, 1908. His habits were good and there was nothing in his family history that had any bearing on the case. About one year previous to his admission to the hospital he had had a "stitch" in his side and was ill for about a week, but made a good recovery. Occasionally he had a slight cough without expectoration, but generally speaking his health was good. Four weeks previous to his admission his clothing became wet through from exposure and the same evening he had chills and fever followed by profuse sweating. He had had similar attacks three or four times previous to admission. One week after the first chill there appeared a swelling over the right forearm, followed the next day by one over the left forearm and right thigh but without any pain or tenderness. When the patient entered the hospital he had a temperature of 100.2°, pulse 120, respiration 24. Blood examination gave leucocytes 11,400; polymorphonuclears 78 per cent.; lymphocytes 17 per cent.; transitionals 2 per cent.; basophiles 2 per cent.; eosinophiles 1 per cent. The urine was clear with a faint trace of albumin, contained many leucocytes, amorphous urates, a few hyaline casts and had a specific gravity of 1022. Physical examination showed a heavily coated tongue, a few sibilant râles over the base of the right lung, and the inguinal and lymph nodes palpable. There was a small abscess over the radial side of the middle third of the left forearm; another of the ulnar side of the right forearm near the elbow; another on the posterior part of the right leg and another over the posterior aspect of the left thigh at the middle third. There were no signs of inflammation and no pain nor tenderness associated with them. These abscesses, which were deeply situated, were opened under cocaine. Culture made upon slanted and coagulated Loeffler's blood serum and on agar tubes remained sterile after a week in the incubating oven. Two guinea pigs were inoculated with the pus, one subcutaneously and the other intraperitoneally. Seventeen days after the inoculation the subcutaneously inoculated pig had developed an abscess, and cultures from the pus revealed Gram negative rods, which closely resembled in their morphology the *Bacillus mallei*. Cultures made from the pus upon slant glycerine agar yielded in forty-eight hours a growth of Gram negative rods, resembling the glanders bacilli in morphology, and guinea pigs inoculated with the pus showed a marked and prompt reaction, dying 36 hours after inoculation. The organism was found in the exudate of both pigs and in culture. The intraperitoneally inoculated pig showed a number of well-encapsulated abscesses in the peritoneum and retroperitoneal lymph nodes, abscesses of the liver and of the skin at the site of the puncture of the needle. Blood culture revealed the bacillus of glanders. The patient ran an irregular temperature until November, when he insisted on returning home. One month later, when seen again, he was running some temperature; two of the wounds were discharging pus. He was having chills and sweats. He was again admitted to the hospital and although the agglutination test was negative and no bacilli were found in the sputum ♏viii glanders vaccine were injected into the gluteal region on January 29. In six hours the temperature rose to 104° F., pulse to 124 and the patient had a severe chill and sweat; there was also considerable reaction in the region of the injection. The temperature gradually came down to normal and the inflammation in the gluteal region subsided. This dose was considered too large, and on February 5, ♏iv were injected as before. After this the temperature rose to 102° and the pulse to 108°. On February 8 ♏iv were again injected and this was followed by a rise of temperature to 105.8° F. and by a chill and sweat. After an interval of five days a similar injection was given. On this occasion the temperature rose to 100°, pulse to 96. The patient insisted on going home and was subsequently treated by Dr. Cramp at the Bellevue Hospital Dispensary. Injections of ♏iv were given on March 1, April 6, April 20, May 4, May 18, June 4 and June 21,

on which occasions there was very little, if any, reaction to the injection. The patient was last seen eighteen months after his symptoms had all disappeared. He had since returned to his own country and no further report was possible. From this case Dr. Cramp concluded: 1. That cases of chronic glanders could easily be overlooked, unless one was constantly on the lookout. 2. That multiple abscesses should excite suspicion, especially if on the extremities, as Robin had shown that in 80 per cent. of the cases such multiple abscesses occurred. That in this case there was no direct association with horses. 4. That the point of entrance of infection was unknown in this case. 5. That there never had been any nasal discharge. 6. That the patient remained apparently cured for six weeks and then showed a return of symptoms. 7. That no bacilli were found in the sputum. 8. That extreme exposure to bad weather seemed to be a predisposing cause. 9. That this case had been proven one of glanders by laboratory methods and by reaction to the vaccine injections. 10. That this case was apparently cured by vaccine injections.

Posterior Root Section for Spastic Paraplegia.—Dr. Ernest Sachs presented a patient, forty years old. For one year she had had a spastic condition which followed an attack of measles. Whether this was a true case of Little's disease or not he did not know. After being in the hospital for some time she was unable to leave her room and could not climb stairs. The first operation performed was a bilateral laminectomy, the third and fourth lumbar and first sacral roots being severed on both sides. Massage and passive motion were given. Now she could get around and climb stairs. There was anesthesia on bution of the nerves from the fourth lumbar segment. The roots were completely cut across at their point of exit. the front of both thighs which corresponded to the distri- She still had ankleclonus.

Frontal Lobe Abscess.—Dr. Ernest Sachs presented a woman who was admitted to the hospital December 20, with the diagnosis of anterior poliomyelitis. She had paralysis of the right arm and leg. Her temperature varied between 99° and 104° F. She had a slight scalp wound on the forehead. A lumbar puncture was made and clear fluid was obtained; it was under considerable tension and the polymorphonuclears were 75 per cent. There were no signs of aphasia. On December 24, she suddenly became unconscious and had convulsions. At this time Dr. Sachs was called in. She soon regained consciousness. There were a weakness of the right arm and leg and diminished reflexes. There was a right optic disc and the vessels were tortuous; therefore, lumbar puncture was again done and 90 c.c. of fluid removed. Diplococci were found and Flexner's serum was injected. The following day she sat up in bed. The diagnosis at that time was a localized meningitis over the left cortex with possible abscess formation. On December 29 the wound in the forehead became puffed and a fracture was discovered. The patient was then sent to Beth Israel Hospital for further treatment. An osteoplastic flap was turned down but it was thought better to put this flap back in place and open the abscess through the original wound in the forehead; this was done. The temperature continued and at the end of one week the patient became somnolent and had retention of urine. A lumbar puncture was again made and in the fluid obtained were found white flakes, probably only fibrin. The patient rallied and made an uneventful recovery. She developed loss of abdominal reflexes on the right side, a symptom described by Stewart in such cases.

Case of Torsion and Strangulation of the Entire Greater Omentum—Recovery.—Dr. Aspinwall Judd presented a man on whom had been made the diagnosis of appendical abscess. He had a temperature of 103° F., pulse 120, leucocyte count 20,000 and a high percentage of polymorphonuclears. There was a mass in the appendical region. At operation there was found a torsion and strangulation of the entire greater omentum producing a volvulus. The end of the omentum was adherent to the appendix and was involved in a catarrhal inflammation. The appendix was engorged but had not ruptured.

A Case of Coincident Right Femoral and Inguinal Hernia in a Man.—Dr. Aspinwall Judd presented this patient who was sent to the hospital because of a hernia of the right side. At operation there was found a coincident right femoral and inguinal hernia. The ordinary operation was performed and an uneventful recovery followed.

A Case of Bacillus Aerogenes Capsulatus with Amputation Five Weeks After Infection, with Recovery.—Dr. Aspinwall Judd reported this case which occurred in Dr. Robert T. Morris's service at the Post Graduate Hospital. So far as Dr. Judd could ascertain this was the only case in which with this delay recovery had taken place. A boy, 13 years of age, was referred to Dr. Judd suffering from a compound, comminuted fracture involving both bones of the forearm. The accident had occurred when the boy was playing upon some manure, and particles of the same contaminated the wound. Bearing in mind that the *Bacillus aerogenes capsulatus* was frequently found in this material he advised prompt incision and cleansing of the wound, and although this was done thoroughly and with great care, within twelve hours gas bubbles arising from the area proclaimed the presence of the dread bacillus. Cultures taken proved the surmise correct, and in addition a virulent culture of streptococcus was found. The inflammation and blebs extended half way to the axilla, temperature had risen rapidly to 104.4° F.; the arm was greatly swollen and edematous and the boy was in great pain. Wide incisions were made through the skin and fascial planes down to the bone from wrist to elbow, both on the anterior and posterior surfaces of the arm. Two long incisions nearly as deep were made in the biceps and triceps. These wounds were cleansed with peroxide of hydrogen, drains inserted and the arm placed in a continual bath of saturated solution of hot alum acetate, the temperature being kept at 102° to 104° F. by means of a spirit lamp. Stimulative and supportive treatment was applied. The arm was taken from the bath twice daily and peroxide injected thoroughly into all the wounds. Fifteen c.c. of commercial mixed vaccines of streptococcus, staphylococcus, and colon bacillus were injected every second or third day. The boy's parents absolutely refused amputation. The temperature diminished and the patient progressed favorably until the twenty-third day when his temperature again rose to 104.4°, the pulse going to 120. Further incisions were made, the bacillus being found as high as the axilla. His temperature varied until the thirtieth day of his illness when a third operation was performed and an infusion of 1400 c.c. of normal saline containing two drachms of adrenalin was administered. At the end of a week the patient was extremely weak, seemingly almost moribund. A second infusion was administered when he was pulseless. Permission to amputate was now given and the entire arm and contents of the axilla were sacrificed. The wound was left wide open and cleansed with peroxide of hydrogen. From this time an uninterrupted, though very slow, convalescence began. During the crisis Fowler's enemata, containing four ounces of saline and half an ounce of whiskey were administered from every three hours to five hours. Considerable quantities of strychnine and digitalin were used and morphine was required on numerous occasions to control the pain. So long as the patient's arm was in the acetate bath he complained of no pain whatever and the aerogenes bacillus apparently made no headway, but as soon as the bath was discontinued on each occasion there was a prompt

recurrence of the infection. How much of the successful issue was due to the continuous alum acetate bath, how much to the liberal use of peroxide of hydrogen, and how much to mixed and autogenous vaccines it was impossible to determine. Perhaps all of these factors together with the extraordinary resistance of the patient were responsible for the outcome.

Dr. J. G. Callison said that the autogenous vaccine was given in doses of five hundred million and six hundred million respectively, and again at a later period injections of three and four hundred million were given on four occasions. After the amputation, when there was considerable purulent discharge, a culture showed the presence of *Bacillus pyocyaneus* with some streptococcus. A vaccine was again prepared, combining these two organisms, and a dose of six hundred million was given. While conclusions could not be drawn from a single case, it did not seem too much to assume that probably the vaccine treatment, by helping to raise the opsonic content of the patient's blood, played a part in overcoming the septicemia, and confined the local infection within narrower limits. The pathologist's report contained also an account of a case of infected wound of the hand in which, after opening an extensive pocket of pus in a tendon sheath, twenty-five cubic centimeters of antistreptococcus serum were given in three doses of four, six, and five million respectively. This case progressed rapidly to recovery, the temperature being normal five days after operation.

Extirpation of the Larynx for Carcinoma.—Dr. Fisher presented a man, forty-seven years old, who first complained of hoarseness in July, 1909. This became worse and dyspnea developed. A diagnosis of carcinoma was made. On August 18 enlarged and diseased glands were extirpated. The trachea was cut across and sewed to the skin; then the larynx was extirpated. The patient made a good recovery from the operation and did well for six days when he began to run temperatures. Three of the tracheal rings became gangrenous. Later he had pain in the lower right lobe of the lung, crepitant râles and a very offensive sputa. On October 5 an abscess cavity was opened; it was about the size of an orange. The temperature then fell to normal. On October 21 the resulting fistula was closed by a plastic operation. Since this the patient had gained forty-four pounds in weight. During the course of his disease a very thick and tenacious mucus was secreted which nearly choked him. This had to be pulled out. The patient now wore a silver tube.

Posterior Spinal Root Section.—Dr. Alfred S. Taylor presented a man, thirty-one years old. When but four years of age he was suddenly stricken with hemiplegia and aphasia. Within the last few years there had developed a spastic condition of the right upper extremity; the cramps and pains in his arm prevented him from getting his sleep. These painful cramps soon occurred every few minutes and, therefore, it was deemed advisable to give him relief by making a section of the posterior spinal roots. Two months ago a laminectomy was done, the last two cervical and first dorsal being completely divided. A very good result followed this procedure.

Posterior Spinal-Root Section in the Treatment of Muscular Spasticity.—Dr. Alfred S. Taylor read this paper. He stated that the theory upon which section of the posterior spinal nerve roots was based was that damage to some portion of the motor mechanism of the central system prevented the passage of controlling and inhibiting impulses from the higher centers to those below. The lower centers freed from such control soon developed a condition of over-excitability or over-activity which caused in the corresponding muscles hypertonus or spasticity. These lower centers were largely accentuated by the stimuli coming along the sensory roots from the peripheral field. This combination of the spinal center with the peripheral sensory and motor components formed the so-called lower reflex arc. The spastic complex involved at least the following elements: 1. Diminished voluntary motor power. 2. Diminished inhibition and control by the upper centers of the reflexes. 3. Over-activity of the spinal centers causing spasticity in the corresponding fields. Different cases were made up of these components in varying degrees. Persistent spasticity often led to fibrous changes in the muscles followed by organic shortening, and this in turn to joint deformities. The prognosis depended upon making the distinction between pure spasticity and organic contracture. The spastic syndrome was characterized by diminished voluntary muscular control, increased reflexes, spastic muscles, resisting either active or passive motion, a certain degree of nervous exhaustion, and the absence of phenomena showing evidences of damage to the sensory tracts. Attempts at voluntary movement aggravated spasticity. Operative interference was contraindicated in those cases which had almost entirely lost the power of voluntary motion, as the elimination of spasticity would substitute a flaccid palsy for the one previously existing. In many of these cases, however, there were conditions present which could be improved by operation. The rigidity of the extremities added to the difficulty of caring for these patients and the severity of the pain made them irritable. Operation relieved this pain and made these cases easier to care for. The object of the operation was to relieve the spasticity by adding a lesion of the sensory tracts to that already existing in the motor, after the analogy of tabes superimposed upon spastic hemiplegia, with the presumed effect of breaking the reflex arc. The point of attack was obviously the intradural portion of the posterior spinal roots, the section of which lying between the ganglion of the root and the cord caused a permanent degeneration upward in the cord. For the exposure of these roots either laminectomy or unilateral laminectomy was employed. Dr. Taylor's personal preference was strongly in favor of unilateral laminectomy, which he had had occasion to use in sixteen cases either for posterior root section or for exploration of the cord. The roots of both sides might be divided through a unilateral laminectomy and he had found, contrary to the statement sometimes made, that this technique was practicable in young children. His youngest patient was three and one-half years old. He first punctured the dura and allowed the fluid to escape slowly, which he believed, would minimize any bad effect. When the posterior roots were freely exposed they might be divided according to one of two plans. Sherren had demonstrated that two consecutive posterior roots could be divided without causing anesthesia or other symptoms. If three or more consecutive roots were divided there would appear anesthesia with more or less trophic disturbance and ataxia. Hence the rule had been laid down that only two adjacent roots should be divided, the next one left, then two more divided, if necessary, and so on. Another way of avoiding undesirable sequelæ was by the partial division, one-half or two-thirds of each root being divided. This method had given good results and avoided disturbance of sensation. To arrive at a logical basis for a choice of method, the groups of spastic muscles must be plotted out with their corresponding nerve roots. When the spastic muscles represented the field of only two or three posterior roots these should be divided completely. When the muscles were spastic over a wide area the writer preferred the method of partial division of the roots involved. In spastic paraplegia, partial section of the roots had one considerable advantage: it was necessary to remove the laminæ from only the last dorsal and two upper lumbar vertebræ to expose the lumbar enlargement of the cord with all the corresponding roots. This made a small wound, placed favorably for healing. The only drawback lay in the fact

that the posterior roots came from the enlargement in a continuous series of small bundles which could not be differentiated into separate roots, so that scientific accuracy was hardly possible. The type of operation should be chosen to suit the individual case. Most operators advised the resection of as much length of the root as was readily possible. If the material was desired for examination this might be done, but otherwise it did not seem necessary. In order to avoid bleeding and the causation of undesirable cicatrices he had adopted the method of crushing the root for a moment with a heavy clamp and then dividing it through the crushed area. These cases seemed to have more pain for the first few days after operation, but the field was much clearer and there was no fear of post-operative organization of clot. After the division of the roots any blood in the dura was flushed out with warm saline solution, the dura closed tight with fine continuous catgut sutures, and the remainder of the wound closed without drainage by layer sutures. Drainage should always be avoided because it frequently led to a prolonged escape of spinal fluid and increased the chances of infection. All of Dr. Taylor's cases except two had healed by primary union. For the first three days there was usually much pain in the operative area. The reflexes diminished in proportion to the disappearance of the spasticity. After the wound had healed there was absolutely no evidence of damage to the spine either in form or function. Organic contracture in some patients occurred in some muscle or group of muscles. The treatment for this condition consisted in the use of the various physical methods of therapy, and in the re-education of the patient in the use of the damaged muscles. After such operative and after treatment practically every case showed great improvement. Of the two cases which resulted fatally one died in the third week of pneumonia and the other during the operation.

Dr. Joseph Fraenkel congratulated Dr. Taylor and Dr. Clark; they had been the first to put the idea underlying this operation into practical use and had brought help to a class of cases which was badly in need of it, and heretofore left to their fate. The operation was to his mind one which had come to stay, and which was a valuable acquisition to the armamentarium of neurological surgery. He believed the operation was in danger of becoming discredited if applied without thorough understanding of the theoretical rationale. This seemed to him to be briefly the following:

In a paper published by Dr. Collins and himself some ten years ago, which was based upon considerable clinical and experimental data, they came to the conclusion that the degree of spasticity and the consequent loss of voluntary motion was the expression of the purity of the lesion of the pyramidal tracts. This meant that an isolated and pure lesion of pyramidal tracts would give rise to considerable spasticity and considerable loss of voluntary motion; that additional disease of sensory tracts would diminish the spasticity and thus also the corresponding defect of motion. Therefore it appeared that the operation was only indicated in cases whose symptomatology was purely motor. In all cases in which there was additional sensory disease, particularly disease of the sensory tracts of the brain, the postoperative results were liable to be disappointing. Thus the disappointing results in the case presented by Dr. Taylor were explained.

Chronic Glossitis of Unknown Origin.—P. Watson-Williams reports the case of a girl, aged sixteen, whose tongue has been sore and fissured for five or six years, but much more so during the past year. There is pain on swallowing, and occasional hoarseness. There is a history of a discharge from the left side of the nose, but no evidence of accessory sinus suppuration. The tongue is extremely fissured with atrophy of papillæ in some parts and hypertrophy in others. There is no actual ulceration, and neither history nor evidence of syphilis.—*Proceedings of the Royal Society of Medicine.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ended February 10, 1912.

	Cases	Deaths
Tuberculosis Pulmonalis	444	181
Diphtheria and Croup	333	27
Measles	868	14
Scarlet Fever	332	16
Smallpox	2	—
Varicella	356	—
Typhoid Fever	53	7
Whooping Cough	31	4
Cerebrospinal Meningitis	7	1
Malarial Fever	—	—
Totals	2,426	250

Pemphigus of Pharnyx and Conjunctiva.—P. Watson-Williams reports the case of a man aged fifty-eight years whose eyes have been inflamed for six weeks, and whose throat and mouth have been sore for about one month. There are white membranous patches scattered over the palate, pharynx, and inner sides of the cheeks and under surface of the tongue. The surrounding mucous membrane is swollen and intensely red. When first seen there was a membranous condition of the conjunctiva, but this has partially cleared up with applications of 10 per cent. argyrol. Finally there appeared bullæ on the chest; these gave the first evidence of skin involvement.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended February 9, 1912.

A STUDY OF THE HEART IN SYPHILIS.*

(BASED ON FIFTY CASES.)

By HARLOW BROOKS, M. D.,

NEW YORK.

VISITING PHYSICIAN TO THE CITY HOSPITAL AND TO THE MONTEFIORE HOME.

In presenting this subject it has been my object, not so much to consider the unusual changes which may occur in the heart in syphilis, but to study the condition of the heat in the ordinary case of this infection.

The importance of the subject must be universally appreciated because of the considerable number of cases of early and late syphilis which ultimately die or develop serious and permanent disease through lesions of this viscus. Because of its anotomical position, and also because of its symptomatic unity, I have elected to consider with the heart the associated disease of the proximal aorta.

Much has been written on this subject but many, in fact most authors, are prone to consider only those lesions as syphilitic which are stamped with the hall-mark of the gumma or which present active changes of unmistakable luetic nature, whereas, concerning other viscera, the kidney or the liver, the resulting fibrosis and degeneration of the late or cured lesions are commonly admitted as really syphilitic. Such is also my conception concerning the late changes in the heart and aorta.

It has been my impression for a long time that internists as a class have not fully appreciated the gravity of the early effects of syphilis on the circulatory organs, because striking signs of cardiac disease may not appear until late in the infection. Doubtless, because cases have ceased to show manifest dermal, mucous membrane or nervous symptoms, we have sometimes treated them in a half-hearted and slipshod sort of way which invites aneurism and courts myocardial degeneration. It is very generally reported that syphilis of the heart does not develop until late in the disease, and, therefore, the condition is of relatively little import in the early stages of the infection. (Krehl, Whittaker, Lang, etc.) I propose to show that this is really not the case, but that it develops early in the infection when only by its prompt treatment permanent cardiac lesions may be obviated.

Since I believe that a study of any disease condition is most satisfactorily based on a thorough knowledge of its pathology and pathological anatomy, I have elected in this paper to present a preliminary study founded on fifty consecutive cases of syphilis taken from my autopsy series, leaving for the future a detailed consideration of the symptomology of the conditions. These fifty cases include secondary, tertiary and quaternary types of the disease, but in passing, permit me to remark that from the pathologists' and internists' viewpoint, the division of syphilis into definite stages is productive only of harm, and it has been borne in upon me not only by my autopsy experience, but from my clinical observations as well, that when the chancre has appeared with general infection, general damage has begun, at least insofar as the circulatory organs are concerned. From this series I think that the most impressive fact shown is that the duration of a case is in reality but little measure of the damage which may be done to the tissues, and especially to the all-important circulatory organs.

Accustomed as are all of us to rely more or less on history in diagnosis, it is perhaps interesting to point out that in but fifteen of these fifty cases was a clear history of syphilis given, yet all showed post-mortem unmistakable and characteristically syphilitic lesions somewhere in the body. Of these fifteen instances mentioned the infection was specifically denied by most, and in some instances entirely honestly, I have no doubt. Of the remaining thirty-five patients luetic history was either voluntarily or unknowingly denied. This observation, which I believe is quite in keeping with the experience of most, but serves to impress upon us the value of scepticism and of the intelligent use of the Wassermann reaction, which, while by no means infallible, either positively or negatively, is certainly better than 70 per cent. of error based largely on history or the therapeutic test.

Because of this discrepancy in history, it has been impossible to estimate in most cases the time which has elapsed between the date of the infection and the appearance of signs or symptoms of cardiac deficiency, or of the post-mortem evidence, but it is quite evident from this study that we can no longer look upon syphilitic disease of the heart as a late manifestation, but that the symptoms of cardiac disturbance seen in the secondary stages doubtless are due to definite morphologic alterations in the heart.

In most instances the only assistance in this regard has come from a study of the lesions. Where these showed active cell production and round cell infiltration, it has been assumed that the change was an acute or still active one, but where it has been characterized more by cicatrization and degeneration it has been assumed that it was of a latter stage, in fact though not necessarily as to time. In several crucial cases, however, to which from time to time reference will be made, the history was such that the time could be determined with a considerable degree of certainty.

From a microscopic study of these lesions I have come to the conclusion that some of the most im-

*Read at the meeting of the Society of Alumni of the City Hospital December 20, 1911.

portant morphological alterations occur in the early stages of the disease, and thus probably account for such early symptoms of cardiac deficiencies as are mentioned by Hirschfelder. (Text-book.)

Changes in the pericardium were found in seventeen of the fifty cases. In no instance, however, were these in any way characteristic of syphilis, and it is my opinion, contrary to that recently expressed by Billings, that there is little or no direct relationship between pericardial lesions and the parent disease, nor do I feel that here, as I have stated elsewhere in regard to non-specific pericarditis, that this condition is in itself a very serious one, but that it appears chiefly only as an index of the nature of the parent process.

Quite a different state of affairs appears to be the case with the epicardium, which was found diseased in twenty-eight of the fifty cases. The nature of this change demands more than passing mention, since it apparently throws light on the whole question of the primary manner in which syphilis affects the circulatory system. The most frequent epicardial lesion is seen in white, opalescent oval or circular patches of thickening, usually situated at points where active capillary anastomoses occur. On microscopic examination these patches of thickening are found in some cases to be made up of hyperplastic endothelial cells and connective tissue fibrils infiltrated by lymphocytes. Beneath these areas the blood and lymph channels are found surrounded by small round cell accumulations, and in some instances calcareous infiltration has taken place. In one instance of this group calcification and diffuse epicardial phlebitis were noted, associated quite naturally with terminal thrombosis of these vessels. These epicardial changes are quite constantly found associated with marked endocardial defects, but are in most cases entirely independent of changes in the pericardium, from which this lesion seems to be entirely distinct even in the matter of mutual adhesions, which, however, rarely seem to originate in this disease. This patchy epicardial lesion is, of course, not exclusively limited to syphilis, but it is in my experience more frequent here than in any other form of disease, and while insofar as I can determine it has no direct or definite clinical manifestations, it is probably an index of vascular disease and is very likely in some respects allied to leucoplakia of the mucous membranes.

Disease of the myocardium is very frequent in these cases of syphilis. This subject has perhaps been most carefully studied by Mracek, who in a group of fifty cases found gummatous myocarditis in ten, fibrous changes in nine, and gummatous and fibrous in eight. Buschke and Fisher (*Deutsche med. Wochenschrift*, Nr., 19, 1906), and Simmons (*Münch. med. Wochenschrift*, 1906, S, 1550) have recently demonstrated the spirochetæ in the diseased muscle.

In my series I have found the occurrence of myocardial changes to correspond relatively, but poorly, with those of Mracek. Actual gumma of the heart I have found, as have Adler, Krehl, and others, a rather infrequent condition, and of my fifty cases true gumma of the myocardium was present in but five instances, but the myocardium was diseased in some manner in forty-four of the fifty cases.

The most frequent myocardial change is fatty degeneration, which was present in ten instances. That this degeneration bears a direct relationship to the lues admits of question, and in my opinion it is in most instances a result of malnutrition of the heart muscle, commonly primarily due to disease of the coronary vessels. Fatty degeneration associated with fibroid change was present in five instances. Fatty and parenchymatous degeneration were associated in six cases. Manifestly syphilis, except in its early and most active stages, will not cause parenchymatous degeneration, and the presence of this type of change in each of these cases was evidently due to entirely extraneous or terminal factors.

Brown atrophy was found alone in seven cases, apparently as an evidence of primary disease of the coronary vessels, which most commonly leads to this state of malnutrition. That this is the correct explanation in these examples is evidenced by the fact that the brown atrophy was found in but one instance unassociated with marked gross disease of the coronary trunks. As a contributory factor, however, it must be remarked that in but one of these seven cases was the age of the patient below forty, and in none was the known duration of the syphilitic infection less than twenty-five years, except in a single case occurring at thirty-four years, where the coronary disease was very marked and active, although the infection was of but six months' standing.

Purely fibroid changes were found in but four instances, but were associated with fatty degeneration and infiltration in five others, so that a total of nine instances may be justly assumed. There is no myocardial change in syphilis which equals in probable importance this fibrosis, and I have made a special study of the condition in an attempt to clear up its origin. Three times it was associated with cardiac aneurism, in all of which this condition had directly or indirectly induced death. In two cases it had particularly involved the very important papillary muscles, and in three other instances it had led to extensive dilation of the right auricle as a result of the fibrous invasion of its walls. Careful microscopic study of hearts taken from cases dying in the active stages of syphilis, or which still show gummata or a true syphilitic myocarditis, has convinced me that this cardiac fibrosis is of two methods of origin. It may, in some cases, result from a coronary thrombosis or obliterative endarteritis, which has led to a greatly diminished blood supply to the myocardium with a resulting myomalacia or muscle necrosis followed and repaired by a consequent fibrosis in the healing process, or it follows from an elemental inflammatory process which has its acute origin as a true syphilitic myocarditis, six instances of which were studied in this series or from the closely analogous condition of cardiac gumma. In the healing and replacement inflammation of luetic myocarditis I have been invariably able to demonstrate active interstitial hyperplasia taking place coincident with or as a result of the specific process. The importance of the recognition of this origin of fibrous myocardial changes is obvious. It at once lays directly at the door of the luetic infection the most important alterations found in the heart muscle in old cases of syphilis, and at the same time it indicates that if earlier death were the rule in syphilis that gummatous or active syphilitic changes would be reported much more commonly, whereas now these changes are but tardily being recognized as frequently occurring, since it is represented at

autopsy by its late signs only. These cases which have come to autopsy in my services have almost without exception been under excellent treatment, at least for a time during the early days of the infection, and may therefore not be expected to show such actual active lesions but rather the evidences or scars of them. What also renders these fibroid changes of syphilis so important is that from the nature of the change, once established, it is ineradicable and although correct and active antisyphilitic medication may cause the clearing up of exudates and the removal of cellular tissue, it is not to be supposed that adult fibrous tissue, unless in a necrotic condition, can be so influenced. Treatment to be successful must then come before and not after these changes.

It has been recognized for a long time that syphilis is one of the chief excitors of coronary disease, but I doubt that most of us yet appreciate the degree to which this is true. In this series disease of the coronaries was present in thirty-five instances *to a relatively greater grade* than the general arterial changes. In other words, a distinct selective tendency of the syphilitic virus for the coronary vessels is manifest. That age is a relatively negligible factor in this condition is indicated by the fact that extensive coronary lesions were found in cases as young as twenty-three, twenty-six, and twenty-eight, and the occurrence as well as the degree of coronary lesions appears to correspond more or less definitely with the activity rather than the duration of the disease.

As to the precise character of the changes in the coronary vessels, nothing definite can be said for it has been found that practically all types of coronary disease are included in this series of cases, from extreme grades of calcification to the acute ulcerative changes of active endarteritis such as was found in an early case in the secondary stage, just as the initial skin rash was appearing. In three instances thrombosis of the coronaries was found which had apparently originated from a primary endarteritis. Speaking in general, the most frequent coronary lesion in syphilis appears to be a fatty degeneration with endarteritis, often with in places a limitation of the lumen, and in others a widening of the same. These changes were found most pronounced in those subjects where a true inflammatory myocarditis with granulomatous formation was present, and the gross examination of the heart wall seemed in those cases to indicate that the granulomatous process had originated in or about the walls of the coronary vessels.

Judging from the considerable number of cases of Stokes-Adams syndrome reported in luetic cases, a frequent location for these myocardial foci is in the auricular ventricular septum and bundle. Two such apparent cases have appeared in my clinical service, but none have thus far come to autopsy. Judging from the lack of response to active syphilitic treatment, these lesions, at least in my cases, are fibrotic or degenerative and not infiltrative in character. They are not the acute primary irritative but curable lesion, but its incurable result. Insofar as may be judged by this series the location of the chief involved area of the myocardium has been mostly dependant upon relationship to a diseased and usually more or less occluded coronary vessel, or upon some endocardial lesion which has thrown an extraordinary strain upon some portion of the heart, for example, auricular thrombosis following extreme auricular dilation and fibrous myocarditis was present in four of my cases in which a valve defect apparently played a determining rôle. Study of these and other cases has also persuaded me that unusual tension upon the papillary muscle is a factor inviting syphilitic invasion to this special muscle distribution.

Endocarditis has been so frequently found associated with syphilis that in the past it has been customary, at least in regard to aortic lesions, to clinically assume where other etiological factors were wanting that the probable exciting agent was syphilis. In this group my findings in this special respect differ somewhat from the rule, although corroborating it in general. Pure aortic lesions do not predominate in this group of cases, and of the thirty-seven instances showing endocarditis seventeen showed involvement of both aortic and mitral segments. In some the aortic lesion was the greater, and in others the mitral predominated insofar as activity was concerned. When pure lesions alone are considered no mitral instances appear, but seven of pure aortic disease are found, most of which showed active ulceration. In three instances the aortic mitral and tricuspid were diseased and the mitral tricuspid and semilunar in one. In three subjects all the heart valves were invaded by a generalized sclerosing valvular endocarditis. In four cases there was a universal involvement of the endocardium, of such nature as to evidence its definitely specific nature, taken in association of course with the general visceral lesions presented in the case.

Involvement of the conus arteriosus and aorta are so closely associated with those of the heart that it seems not improper to consider lesions of these structures together. The aorta was diseased in a total of forty-four out of fifty cases, in thirty-seven only, however, did the disease extend to the abdominal artery and its chief branches; in short, a definite predeliction for the upper portion of the vessel was shown. In ten cases aortic aneurysm was found, giving, I believe, one of the highest percentages of aneurysm formation yet reported. None of these showed aneurysm below the diaphragm, but all were limited to the arch, again indicating the affinity which the syphilitic poison has for this region of the aorta. Two aneurysms developed from the sinuses which I have found in many cases, both specific and simple, to show more or less distention and ulceration even where no true aneurysm can be said anatomically to exist. Three were of the ascending arch, one of the ascending and transverse, and one of the transverse only, while in three instances the sac was of such size as to practically include all parts of the arch.

It has long been a matter of dispute as to how soon after primary infection aneurysmal formation might take place, and in general my cases conform to the rule that it is in the late disease that it occurs; for example, in two cases where the time of infection could be fairly certainly fixed the aneurysm was discovered in one twenty-two years after infection, and in the other thirty-two years. On the contrary, in two other cases of this same group the aneurysm developed in one not over six months after the initial lesion, and in another, a most interesting case, the patient died from the perforation of an aneurysmal sacculation from one of the aortic sinuses at the very outset of the secondary skin rash even before the diagnosis had been conclusively made. This finding explains the observation and statement of Grassman con-

cerning the frequency with which serious cardiac signs appear in the secondary stages of syphilis, and in my conclusions I shall use this fact as of special importance for the adequate understanding of syphilis of the circulatory organs.

So much has already been written concerning the various forms of aortic disease which occur in syphilis that it is unnecessary to consider them at any very great length here; in my series, however, the predominating lesion, appears to be an atheromatous process in which calcified plaques alternate with excavated and degenerated foci. In most instances the lesions do not, however, possess any grossly syphilitic characteristics, but might also be caused by other disease processes, although when examined microscopically some of the foci commonly exhibit areas of infiltration about the vasa vasorum and necrotic centers which must be looked upon as more or less typically syphilitic. Twelve cases showed changes of this suggestive nature. In eleven other instances the aortitis was of the ordinary arteriosclerotic character, which insofar as could be determined presented no certain hall-marks of lues. Active inflammatory changes, probably of a syphilitic character, were found in two cases and in four the inflammation was definitely of a gummatous type, evidenced by nodules of mingled organized tissue and clot in which giant cells and foci of necrosis with fibrous hyperplasia left no doubt as to their nature. Six instances presented discrete foci of fatty necrosis of the intima extending down to the media coat, and sometimes into it. Very little inflammatory reaction attends these lesions, the surface of which is often raised above the mean level of the intima and which are marked grossly by a bright yellow color. Lesions of this character are also very likely to be distributed along the descending aorta and are often symmetrically placed near or about the exit of the intercostal arteries.

There can be but little doubt that the primary change induced by syphilis on the heart and aorta originates in and about the nutrient blood vessels of these viscera. This is indicated both by the changes in the epicardium and by those in the myocardium which can, in most instances, be directly and anatomically traced to the blood vessels. Nothing is more clear from a pathological standpoint than that the myocardial degenerations are commonly dependent on preliminary alterations in the coronaries, and the almost constant changes in these vessels is one of the most striking features of the disease, as it affects the circulatory system.

The early predilection of the syphilitic poison for the blood vessels may perhaps want experimental evidence as yet, but the tendency for this infection to seriously involve the vascular distribution is among the earliest of scientific anatomical observations concerning syphilis. It was recognized and described definitely by Ambrose Pare and by Lancisi in 1728.

Concerning the important question then of how soon the heart begins to suffer fom the effects of syphilis, Krehl states (Nothnagel's Ency. Diseases of the Heart. Am. Ed.) that this is not before six to ten years after infection, yet Grassman. Hirschfelder and others call attention to the frequency with which serious cardiac signs appear during the secondary stage. This is a common observation as well as the prompt improvement which occurs under proper treatment. Certainly from my cases one must infer that these changes begin at least early in the secondary stage of the disease, although they may not fully develop until the tertiary stage. The case cited above in which an aneurysm perforated before the secondary rash had fully appeared and that in which serious cardiac and aortic lesions sufficient to cause death developed within six months after infection are in all probability not isolated and rare cases, but the treatment which is generally administered at this period seems at least to relieve and often to thus obscure or delay the symptoms in the average case. Most syphilitic infections are recognized during the secondary stage and are at least for a time correctly treated, so it seems probable that the cardiac and aortic lesions are thus held at least for a time in abeyance. Recognizing as we must the very early onset of vascular changes in syphilis and the fact which I have also attempted to demonstrate is apparent that most of the cardiac lesions are secondary to these primary vascular alterations, it follows then that cardiac lesions are early in development. Absolute anatomical confirmation of this theory is chiefly wanting because cases do not ordinarily die during this early period for the patient survives the acute and curable lesion to suffer and very probably eventually die from its late results which from the nature of the lesions and from that of the tissue in which they occur are permanent.

Most of the cases reported in this series have come from hospital services where the nature of the case had been fully appreciated notwithstanding the almost universal denial of history on the part of the patients, hence it appears that these serious late lesions of the heart and aorta do not respond to treatment, for in nearly all these cases the cardiovascular lesions were an important or the sole factor in the causation of death. Hence appears the great necessity for instituting early and vigorous treatment in all cases of syphilis as soon as they are recognized and before permanent lesions may develop in these important organs. The earlier and the more vigorous, just so much the better, for the above cases have demonstrated how hopeless treatment must be in cases already showing extensive coronary changes or a fibroid or degenerated myocardium.

Notwithstanding the apparent hopeless character of such lesions as have been described in this paper it none the less not infrequently happens that properly instituted treatment even in the late stages may afford a certain amount of benefit. Years ago Curschmann reported good results from the exhibition of iodine in cardiovascular syphilis, but it has become necessary to reaffirm this almost axiomatic observation as indicated by the recent articles of Longcope and of Collins and Sachs (Reports Assn. Am. Phys., 1910), who have called attention to the fact that spyhilitic disease of the circulatory organs demands active treatment with mercury—pushed just as vigorously as in acute syphilis of the central nervous system.

As Krehl has well said of this subject, the clinical signs are not characteristic; they are simply those of a myocarditis or of an aortitis, or those of a coronary sclerosis, yet when these signs appear and any possibility of syphilitic infection be present the case should be given the benefit of the doubt disregarding the age of the probable lesion, though fully appreciating that to be entirely effective, treatment should have been begun long before symptoms appear.

Thanks to the Wassermann reaction we are no longer dependent on an uncertain and probably untruthful history to guide us in this respect, and my plea is that in all cases of probable aortic or cardiac disease the Wassermann test be applied and then that active treatment be kept up at least until a negative Wassermann is attained. In the absence of a positive Wassermann I would further advise that if the clinical picture indicates syphilitic infection that the treatment test be vigorously applied none the less.

Further, I wish to again point out to you that if real permanent benefit is to be expected in these cases, treatment must be instituted very early, probably early in the secondary stage, and the drugs must be pushed to their full physiological limit.

I believe that internists as a class are very negligent in their management of cases of syphilis—we are all too apt to feel with the patient that as long as the external manifestations of the disease are in abeyance all is well, while as a matter of fact the intravascular changes are far more important, far reaching, and resistant than the signs of the mucous membranes and skin.

As to the methods of treatment, from my personal observation, salvarsan is no more dangerous in cases of marked cardiovascular disease than in other and seemingly simple cases, but this paper is not designed to discuss the methods of treatment but to call your most earnest attention to the almost universal occurrence of serious cardiac and aortic lesions in syphilis, to the fact that these changes begin early in the infection and through their latter stages they possess a largely irradicable character and from the very nature of the lesions and their visceral location the bearing on not only health but on life itself is more direct and important.

44 West Ninth Street.

THE QUANTITATIVE ESTIMATION OF TRYPSIN AND AMYLASE IN THE FECES AND IN DUODENAL CONTENTS.

PRELIMINARY REPORT.

By G. A. FRIEDMAN, M.D.,

NEW YORK.

Volhard's method of showing the presence of trypsin has already enabled us to obtain valuable data with reference to the occasional regurgitation of pancreatic juice into the stomach. Thus, Faubel was able to show the presence of trypsin in twenty-two out of thirty-seven cases, having pumped out the stomach in these cases after the introduction of oil. Volhard himself found tryptic activity in nine cases out of twelve of stomach contents obtained in the same manner. In one case of severe icterus he was able to exclude carcinoma of the head of the pancreas because of the strong trypsin reaction of the stomach contents. In a patient with severe diabetes, in which he could never obtain any evidence of the regurgitation of pancreatic juice into the stomach, his diagnosis of sclerosis of the pancreas and obstruction of its duct was corroborated at the autopsy.

Molnar has studied the presence of trypsin and pepsin in the stomach contents, giving oil to his patients on a fasting stomach and using Volhard's method of determining trypsin. The largest values for trypsin were obtained in gastroptosis and gastric carcinoma. Volhard's method (for which the reader is referred to his paper), combined with Wohlgemuth's method of quantitative estimation of amylase in the feces, has led in many instances to the diagnosis of various affections of the pancreas; Volhard, Goldschmidt, Heyn, and others have published such instances. On the other hand, the quantitative determination of trypsin and amylase in human duodenal contents with the parallel estimation of these ferments in the feces has, to my knowledge, never before been made. I have used the feces of eighteen patients, making several estimations in certain cases and, when possible, making a previous analysis of the stomach contents. In five of these cases the duodenal contents were likewise examined by the same methods; Einhorn's duodenal pump being used for obtaining the necessary material. This pump reaches the duodenum easily if there is no obstruction of the pylorus and no considerable atony of the gastric musculature. It is surprising how fast the olive-shaped end of the pump reaches the duodenum in cases of achylia gastrica, this being of course explained by the frequent hypermotility accompanying this affection. It is advisable in using Einhorn's pump not to aspirate at once when the mark 80 is reached, but to wait for about an hour. Then one usually obtains, even in cases of gastric hyperacidity, neutral or weakly alkaline duodenal juice, which is golden yellow in color as a rule, though occasionally colorless. Only in duodenal contents obtained under such conditions is pepsin not to be demonstrated, as I have often proved to my satisfaction by the use of the Jacoby ricin test. Feces are also usually free from pepsin except in isolated cases, as was lately shown by Ury. I have accordingly used the less complicated method of Fuld-Gross-Goldschmidt in preference to Volhard's method, which serves to show both trypsin and pepsin, which, of course, was necessary in his patients, in whom gastric juice with regurgitated pancreatic juice was the material used for examination. Previous to my work, Heyn has successfully used this method for determining ferments in the feces, and then simply adopted it for the examination of the duodenal juice as well.

The following was the method of examination. The patient was kept on a mixed diet for three days, after which the feces were always of slight alkaline reaction. For testing this reaction Kaplan's method was used, as follows: Rub up five grams of feces in 30 c.c. of distilled water, added gradually to the feces. To 2 c.c. of this mixture, placed in a test tube, 1 per cent. alcoholic phenolphthalein solution was added and titrated with decinormal soda hydrate. If 0.9 c.c. or less of the soda hydrate solution is necessary to produce a distinct change in the feces then the reaction may be considered alkaline. Five grams of dried feces of such patient was then rubbed up with 20 c.c. of physiological salt solution added drop by drop, and then centrifuged for fifteen minutes in a high speed centrifuge, filtrated through a double paper filter and the filtrate was used for further examination. Now two series of dilutions were made with distilled water 1:5; 1:10; 1:50; 1:100; 1:1,000; 1:10,000. To one series 5 c.c. of a 1:1,000 casein solution are now added.* To the second series of dilutions 5 c.c. of 1 per cent. soluble starch (Kahlbaum) and a little toluol are added. The test tubes are closed

*One gram of casein, 1 gram of sodium carbonate, and 1 gram of chloroform are mixed in 1 liter of distilled water and then heated on a water bath.

with cotton and then incubated for twenty-four hours at a temperature of 38° C. Now a few drops of 1 per cent. acetic acid are added to the test tubes containing casein: turbidity or precipitate means that the casein has not been digested. In order to interpret the results in terms of units, the following calculation was used: A dilution of 1:50 of the feces extract digests 5 c.c. of casein solution. One c.c. of undiluted feces should digest fifty times this quantity, that is, 250 "casein units." The second series of test tubes are filled with water and one drop of ⅒ iodine solution is added. A blue coloration shows that the starch has not been all digested. The same calculation is used for translating the result into "amylase units." The same method is used in testing duodenal juice, this being first filtered and diluted with distilled water. To differentiate the results, we call them "duodenal trypsin" and "duodenal amylase" units. The duodenal juice is obtained three-quarters of an hour after giving the patients a glass of milk half diluted with water and sweetened with two lumps of sugar.

My material has been obtained from the Vanderbilt Clinic, a few cases from Mount Sinai Dispensary, and the rest from private practice.

Case I.—W. was referred to me by Dr. T. C. Janeway with a probable diagnosis of catarrhal icterus. The stool was examined five times—twice when icterus was still present and three times after this had subsided. The icterus lasted eight weeks and had existed for six weeks when the patient was referred to me for examination. First examination of stool: trypsin, 25 units; amylase, 500 units. Second examination (a week later): trypsin, 50 units; amylase, 500 units. Third examination (a week later): trypsin, 250 units; amylase, 500 units. On the last occasion the icterus was no longer present, except that the conjunctivæ were slightly tinged yellow. During that week the stomach content was examined twice: free HCl, 60-64; total acidity 90-90; starch digestion, blue color obtained. On the day of the third examination of feces the duodenal tube was introduced. Contents: golden yellow, trypsin 50,000, amylase 5,000. Fourth examination of stool (a week later); trypsin 5,000, amylase 500. Duodenal examination on this occasion showed, after the same meal, trypsin 500,000, amylase 500. Fifth examination (one week later): Feces: trypsin 5,000, amylase 5,000. Duodenal contents: trypsin 5,000,000, amylase 5,000.

Case II.—H. (Vanderbilt Clinic) has been under my treatment for a considerable time for achylia gastrica. While taking HCl, the diarrhea is arrested, on discontinuing it returns. First examination of feces: trypsin 250, amylase 50,000. Duodenal contents colorless, reaction neutral, many milk coagula, trypsin 50, amylase 5,000. Second examination of feces: same results. Ten minutes after aspiration of 20 c.c. of duodenal contents the following test was made: 10 drops of a 10 per cent. HCl solution were injected into the duodenum with half a syringe of water; aspiration 10 minutes later. Golden yellow color, strong acid reaction, less milk coagula. After 15 minutes contents again aspirated and were colorless. Reaction neutral. Milk coagula smaller and fewer.

Case III.—Mrs. H., referred to me by Dr. Lachowsky. Achylia gastrica and gastrogenous diarrhea. Right floating kidney, high degree of secondary anemia, nervous symptoms. First examination of feces: trypsin 50, amylase 5,000. Duodenal contents: golden yellow, milk coagula. Thin, stringy mucus adherent to the duodenal bucket (duodenal catarrh (?)). Trypsin 50, amylase 50,000. The feces were no longer examined. The duodenal contents were examined three times more at intervals of 2 weeks. Administration of HCl with pepsin, alternating with pancreatin. General condition much better. No more diarrhea, but the same trypsin and amylase values. There was no mucus in any of the three subsequent examinations.

Case IV.—P. Achylia gastrica and constipation. First examination: Feces, trypsin 50, amylase 5,000. Duodenal: trypsin 50, amylase 5,000. Contents golden yellow, reaction alkaline, few milk coagula. The next three examinations of feces and duodenal contents at intervals of one to two weeks resulted in the same values, except that the reaction of duodenal contents was sometimes strongly alkaline, sometimes neutral; color twice golden yellow, once colorless.

Case V.—Miss F. Achylia gastrica, diarrhea, mucous colitis. First examination of feces: trypsin 50, amylase 250. Second examination: trypsin 50, amylase 250. Duodenal contents: trypsin 50, amylase 5,000.

Case VI.—R. Gastrophtosis. Free HCl 44. Total acidity, 84. Starch, blue color obtained. Feces: trypsin 5,000.

Case VII.—M. Intestinal atony. Hyperacidity. Neurasthenia. Trypsin 500, amylase 500.

Case VIII.—F. Hepatic cirrhosis (?) Trypsin 500, amylase 500.

Case IX.—G., 27. Gallstones. Had a few attacks of typical gallstone colic shortly before examination. Trypsin 500, amylase 500.

Case X.—C. Cholecystitis (?) Incomplete pyloric stenosis. Hyperacidity. Trypsin 50, amylase 50.

Case XI.—D. (Vanderbilt Clinic). Violent paroxysms of gallstone colic five years ago. Six weeks ago icterus set in with brown urine. Patient does not know whether the onset of icterus was accompanied by clay-colored stools. In the sixth week of her icterus there was violent vomiting, occurring mostly at night. Since then there has been also dull pain in the hepatic region. Has lost weight. Present condition: Icterus, but not much pronounced. Liver enlarged. Right hepatic border can be palpated down to two fingers' breadth above umbilicus. Left lobe not palpable. Surface of liver is nodular and very hard. Gall-bladder cannot be palpated. Examination on a fasting stomach yields 230 to 280 c.c. of acid reacting contents with food remnants. Contents in two layers after standing, lower consisting of food remains. There is a marked bile reaction. Microscopically, there are concentric starch granules and many sarcinæ, both of the large and the small varieties. Congo, positive; Günozburg, positive. Bile-ring Ewald. Free HCl, 20; total acidity, 48. Glycyltryptophan test negative. Starch digestion, blue color obtained. Urine, brown; bile, present. Stool, clay colored. No biliary pigments. Trypsin 25, amylase 50. Diagnosis: Probable primary carcinoma of the gall-bladder with secondary partial stenosis by pressure of the first part of the duodenum, with possibly secondary nodules in the pancreas. In the Presbyterian Hospital the stool was examined for neutral fat and fatty acids, the former being found in excess. The patient being very weak, exploratory laparotomy was done under novocain anesthesia. No information could be gained in reference to the pancreas and gall-bladder.

The latter was probably shrunken; nodules in the liver and omentum could be distinguished.

Case XII.—B., tailor. Abdominal tumor in the right hypogastrium. Diagnosis lies between mesenterial, omental, or pancreatic neoplasm or cyst. Examinations of the stomach contents gave normal acidity values. Feces: trypsin 500, amylase 5,000. For this reason pancreatic cyst was partly excluded. Operation in the Mt. Sinai Hospital (Dr. Elsberg). A thick-walled cyst of the omentum, filled with blood, was found. Pathological examination: Spindle-celled sarcoma.

Case XIII.—G. From the Mt. Sinai Dispensary. Visible intestinal peristalsis up to the cecum, where a tumor is distinctly palpable. Cachexia. Reaction for occult blood positive. Stool contains long bacilli. Very large quantities of pus cells in the stool. Examinations of the stomach contents: Hyperacidity. Trypsin 50, amylase 50. Diagnosis: carcinoma of the cecum.

Case XIV.—S. From the Vanderbilt Clinic, referred by Dr. Mosenthal. Light diabetes. Gastric juice: Alternating anacidity and hyperacidity (heterochylia). Trypsin 500, amylase 50,000. The same results were obtained on three occasions.

Case XV.—B. Diabetes (3½ per cent. sugar). Trypsin 500, amylase 5,000.

Case XVI.—A. Referred by Dr. Waldman, New York. Colica arteriosclerotica. Pulmonary tuberculosis. Achylia gastrica. Severe diarrhea. Trypsin 25, amylase 25. On account of severe attacks of abdominal pain an exploratory laparotomy was performed January 30, 1911, for gastric cancer. Nothing was found. August 17, first seen by me. Pulsation of the abdominal aorta marked. Blood pressure taken on four occasions: 160, 158, 145, 170. No cough, no fever. Lungs negative. In subsequent examinations subcrepitant râles found in right axillary region. In October, consolidation of this region and left apex. Cough. Many tubercle bacilli in the sputum. At first the attacks of pain were greatly relieved by diuretin in 0.5 gram doses. Stools not clay-colored. Urine negative.

Case XVII.—G. Chronic nephritis (after scarlet fever). Enlarged spleen after malaria, in Russia. Chronic colitis. Trypsin 5,000, amylase 5,000

Case XVIII.—M. Bulimia for 20 years. Operation for gallstones five years later. During the last three weeks violent diarrhea, with clayish appearance of stools. No tenia eggs or parts were found in many preparations. Right floating kidney. Urine negative, no biliary pigments. The stools look exactly as in obstructive icterus, yet bile was present. Microscopic: Muscle fibers with and without transverse striæ, no crystals of neutral fat, yeast cells, triple phosphates, many pus cells. Blood: Considerable secondary anemia. This suggested chronic pancreatitis (history of gallstones). Examinations of the stomach contents: No free HCl. Lactic acid, reaction strongly positive. Long bacilli. Glycyltryptophan test positive twice. No microscopic or macroscopic stagnation. Possibly this was a case of ulcerative carcinoma of the gastric wall, and hence the diarrhea, which would account for the high values: trypsin 500, amylase 50,000. The trypsin and amylase findings, as well as the analyses of gastric contents, etc., are tabulated in tables A and B:

Analysis of Findings.

Group A.—Case I is interesting from the fact that the icterus subsided as the trypsin units gradually rose from 25 to 5,000, while the amylase values remained uninfluenced by the jaundice. Furthermore, it is a striking fact that in the duodenal contents the trypsin values were as high as 50,000 to 5,000,000 and the amylase units relatively low. If Pawlow's animal experiments are remembered, showing that HCl incites secretion of the pancreas ferments and bile, the high trypsin units in the duodenum after the abatement of icterus could be easily explained, because in this patient there was hyperacidity of the gastric contents. Unfortunately the duodenal contents could not be examined at the first two examinations when icterus was present, but the increase in the trypsin values of the feces seems to point to an obstruction of the secretion at the time, probably a catarrhal swelling of the pancreas duct, or ducts, because the stimulus, HCl, inciting pancreatic secretion, was certainly present. In cases II, III, IV and V (achylia) the low value of the trypsin units in the feces and duodenum is noteworthy, while the amylase units are high as compared to case I. Here it may be assumed that the pancreas has not ceased to supply the protryptic secretion or its way to the duodenum has not been obstructed, but that the stimulus for the secretion was absent. The good starch digestion in the stomach in achylia is also demonstrated. The findings in

VII.	M.	Intestinal atony	Hyperchlorhydria	500	500
X.	A. Referred by Dr. Bobrow.	Incomplete pyloric obstruction; cholecystitis (?).	Hyperacidity and hypersecretion. Microscopical stagnation of food on fasting stomach.	50	50
VIII.	F. Vanderbilt Clinic	Probably cirrhosis of liver	Hyperacidity	500	600
XI.	D. Vanderbilt Clinic. Also seen in the Presbyterian Hospital.	Probably primary carcinoma of gallbladder with pyloric or duodenal obstruction. Obstructive icterus. Nodular hard liver.	Free HCl, 20. T. A., 46. Lactic acid, 0. Glycyltryptophan test negative. On fasting stomach 230-280 c.c. obtained. Gross and microscopic stagnation of food. Sarcinæ. Marked bile reaction.	25	50
IX.	G.	Gallstones	Hyperacidity	500	500
XII.	B.	Omental cyst	Free HCl, 20. Total Acidity, 50	500	5,000
XIII.	G.	Carcinoma of the cecum	Hyperacidity	50	50
XIV.	S. Vanderbilt Clinic. Referred by Dr. Mosenthal.	Diabetes mellitus	Heterochylia	500. On two subsequent determinations there were the same findings.	5,000
XV.	B.	Diabetes mellitus, 3½ per cent. sugar, reported by Dr. Bernstein.	Not made.	500. On two subsequent determinations the same findings.	5,000
XVI.	A. Seen also by Dr. T. C. Janeway.	Colica arteriosclerotica. Pulmonary tuberculosis. Diarrhea alternately with constipation.	Anacidity on two occasions	25	25
XVII.	G.	Chronic nephritis after scarlatina. Tumor of the spleen (malaria in Russia). Chronic colitis with profuse diarrhea.		5,000	5,000
XVIII.	M.	Carcinoma of the stomach, ulcerated, probably of the walls. Diarrhea.		500	5,000

case II, after administration of HCl through the duodenal tube, deserve special consideration. The rapid change of color to golden yellow proves an increased secretion of bile followed by its typical action (milk coagula smaller and fewer). With the disappearance of the acid reaction the secretion of bile was arrested (contents colorless). In case III mucus in the duodenal contents could be demonstrated once. But I consider it hasty to conclude from this fact that there was cartarrhal duodenitis. The patient was very nervous, and the case may have been similar to cases of mucous colitis of nervous origin. In the *American Journal of the Medical Sciences* I have described a case of Reynaud's disease with intermittent achylia gastrica in which mucus was occasionally present in the stomach, while at other times it was completely absent. With the exception of case III I have never observed mucus in the duodenum. In cases VI, VII, VIII, and IX the feces contain normal values. The low values, in spite of hyperacidity, are remarkable in case X, and it is open to question whether we have to deal with secondary chronic pancreatitis in this patient. In case X there were probably metastases in the pancreas. The excess of neutral fat in the feces certainly points to a pancreatic affection. It is hard to believe that there was a primary carcinoma of the pancreas, because, in the first place, there was a typical paroxysm of gallstone colic, and, in the second place, the icterus was not as pronounced as is generally observed in primary carcinoma of the head of the pancreas. It may be concluded from the findings in cases XIV and XV that the diabetes was not of pancreatic origin. Cases XVII and XVIII confirm the results obtained by other investigators, who have found high trypsin and amylase values in severe diarrhea, while case XVI provides an exception, there being diarrhea and yet very low values. Considering, however, that in this case anacidity had previously existed, it would be possible thus to account for the low trypsin values, but not for the amylase figures.

In conclusion it must be mentioned that Frank and Schittenhelm rightly assert that with the newer methods of examination it is possible only to demonstrate a proteolytic ferment, but by no means to establish the fact that that ferment is surely trypsin. for this reason they suggest that control experiments with leucylglycin be made, as this preparation is split by erepsin with the formation of glycocoll, but not by trypsin. I purpose making experimental comparisons in this respect in the near future. Up to the present I have not been able to obtain leucylglycin in New York. I herewith express my hearty thanks to Dr. T. C. Janeway, in whose private laboratory most of the work here described has been carried out. My thanks are also due to Mr. W. W. Herrick, chief of the Internal Medical Department, Vanderbilt Clinic, where many of these patients have been examined.

123 EAST NINTY-FIFTH STREET.

COLON BACILLUS INFECTION OF THE URINARY TRACT.

REPORT OF CASES.

By REGINALD M. RAWLS, M.D.

NEW YORK.

ASSISTANT SURGEON WOMAN'S HOSPITAL; GYNECOLOGIST TO NORTH-WESTERN DISPENSARY; PHYSICIAN TO DEMLIT DISPENSARY.

In a recent article (MEDICAL RECORD, Oct. 7, 1911) I drew certain conclusions from a review of the literature and from my study of cases. In two years, in a surgical experience, I have observed eighteen cases, of which seventeen have been seen in the last fifteen months. These cases have all presented definite clinical symptoms and have shown the *Bacillus coli* present in cultures made from the urine. I shall report but eight of these cases, which will be sufficient to show that the *Bacillus coli* may be the cause of acute urinary infection in health, in the puerperium, and in post-operative gynecological cases. While my series is too small to permit definite conclusions to be drawn, it proves that this infection is not uncommon and that hematogenous infection is quite common. *Bacillus coli* infection of the urinary tract may be primary or it may be secondary to some other focus. Often the first clinical evidence of this primary focus is an acute infection in the urinary tract.

CASE I.—Male, age 36, pneumonia ten years ago, no venereal history. Middle of August, 1909, marked gastrointestinal disturbance, general malaise, and pain in right kidney. Two weeks later a rigor lasting half an hour, fever, sweating, mild prostration, increased right lumbar pain, and frequent and painful urination. For a few days the patient had a recurring afternoon chilliness and temperature, but was able to be up and attend to his usual occupation.

Evening of September 2 he had severe chill and a temperature of 103.5° F. with symptoms of acute renal colic. The next five days an evening chill or chilliness, temperature 104° to 104.2°, pulse 70 to 100; the morning temperature ranging from 101.5° to 103°, pulse 80 to 82. The pulse was often irregular and weak and occasionally of high tension during a mild suppression of urine. There was frontal headache, and during the pyrexia much general discomfort, restlessness and mild delirium. A troublesome cough with mild physical signs developed, clearing up six days later with a large quantity of mucopurulent sputum. For one day there was a mild right otitis media which terminated without suppuration. *Urine* was amber colored, turbid, strongly acid, sp. gr. 1011, albumin 0.77 grains to the fluid ounce, no sugar, one epithelial and two finely granular casts, moderate amount of pus. Diazo and Widal reactions negative. Leucocytes, 14,000; Polymorphs, 85 per cent. General symptomatic treatment was given with urotropin, grains 5, every four hours. Five days later (Sept. 14) temperature remained normal and patient made a slow convalescence and was able to take up his usual occupation the end of September, although the urine was still turbid and there was some slight lumbar pain and frequency of urination.

Three weeks later, Oct. 20, he developed a right epididymitis, and two days later was confined to bed as the pain was intense. Temperature was 102° to 103°. A urethral discharge developed and a smear showed the colon bacillus. Abscess of the epididymis was incised and culture from the pus showed pure colon bacillus. Two weeks later, when all active symptoms had subsided, autogenous vaccines, one hundred million, was given on five successive days. Slight local reaction and one degree rise in temperature. On the sixth day, five hundred million given, slight local but no general reaction. Urotropin was given in five grain doses every four hours, increasing five grains a day up to 75 grains, and then 30 grains a day for a period of several months. The vaccine seemed to have no effect on the bacteriuria and the urotropin, even in large doses, only a temporary effect; the frequency of urination, however, was marked, especially with the maximum dose. At the present time there is a bacteriuria and occasional lumbar pain. An x-ray photograph gave no evidence of stone or any kidney abnormality.

CASE II (5140).—Female, age 22. For two or three years attacks of colitis. One year ago had "sugar in the blood" and colitis; confined to bed two weeks. Morning of August 23, 1910, normal confinement, slight perineal laceration, repaired seven hours later. Twelve hours after delivery a chill and temperature. Seen in consultation afternoon of August 24, temperature 102.8°, pulse 108, slight abdominal distension, tenderness over uterus and bladder, but no tenderness over kidneys. After thorough catharsis symptoms subsided, except for an afternoon chilliness and slight rise in temperature. The fourth day post-partum the left parotid became enlarged and painful. The next afternoon a severe rigor, temperature 104°, severe headache, and increased swelling and pain in parotid. The following afternoon I again saw the patient, the lochia were more profuse and foul, uterus enlarged, and there was marked tenderness over uterus and bladder.

Admitted to Woman's Hospital, August 31, 1910, at 8 A. M., temperature 101.8°, pulse 112, respiration 28. Urine, amber, acid, sp. gr. 1019, trace of albumin, no sugar, hyaline casts, pus, and bacteria. Culture from urine showed pure *Bacillus coli*. Leucocytes 21,400, polymorphs, 87 per cent. Blood culture negative.

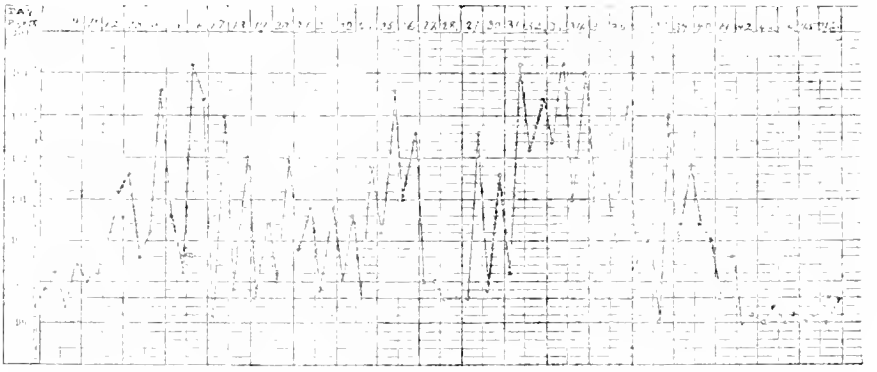
Under ether, the cervix admitted two fingers and was discharging a large amount of pus with strong putrid odor. The uterine cavity was explored with gloved finger and Emmet curette forceps and a small amount of débris, principally old blood clot, was removed. The fundus was located half way between umbilicus and symphysis. The uterus was very flabby, its walls thin, and in places there were distinct lines of cleavage extending from the cavity out into the musculature. The examination impressed me that I was dealing with a very septic uterus and that the prognosis was decidedly bad. The uterus was douched out with iodine water, and an application of tincture of iodine made and the cavity packed with iodoform gauze. Culture from the uterine cavity showed pure *Bacillus coli*. Urine, after ether examination amber, acid, sp. gr. 1017, trace of albumin, no sugar, coarse granular casts, and pus. Leucocytes 25,500 and polymorphs 88 per cent.

The first twenty-four hours temperature ranged from 102.8° to 104.6°, although five alcohol sponge baths, Murphy drip, strychnine, and ergotol were used to relieve symptoms. Next morning uterine gauze removed and for first time there was noticed a marked urticaria of neck, arms, and thighs, which disappeared in two or three days.

The second twenty-four hours, temperature ranged from 103° to 104.6°, although urotropin and benzoate of soda, āā grains 70, strychnine, ergotol, and five alcohol sponge baths were given. There was painful urination with slight tenderness over right kidney, especially over the costovertebral angle. Urotropin and sodium benzoate continued and temperature steadily came down with a marked decrease in size of parotid and decrease of vaginal discharge, and at end of five days remained normal. Sixteen days later patient was discharged. Urine was normal, except that it gave a pure culture of *Bacillus coli*. Smear and culture from cervix negative.

Case III.—Mrs. B. (6435), admitted to Woman's Hospital, June 26, 1911. Age 26, nullipara. Dysmenorrhea and for two years very nervous, frequent headache, backache, and pain in right lumbar region. At times frequent and painful micturition. Uranalysis: Amber, acid, 1020, no albumin, no sugar, epithelial and pus cells.

June 29, 1911, Pfannenstiel incision, resection of right ovary, and shortening of round ligaments through external ring. Uneventful postoperative recovery until twelfth day, when there was a slight rise of temperature, which reached 101.6° the morning of the thirteenth day. (See temperature chart.)



Accompanying this fever were headache, sore throat, pain in the back and right kidney. A simple gargle and aspirin, grains ten every four hours, were used and the temperature fell to 99.6° by afternoon. In twenty-four hours (14th day) there were a chill, sweating, headache, photophobia, marked general discomfort, and the temperature, pulse, and respiration were 103.6°, 116, and 28, respectively. An ice cap and alcohol sponge bath were used, in addition to the aspirin and the temperature in twenty-four hours (afternoon of 15th day) fell to 99.2°. Blood examination: Leucocytes 18,000 and polymorphs 81 per cent. Smear from throat was negative. Uranalysis: Dark amber, alkaline, 1010, albumin a cloud, no sugar, pus and blood cells. Culture from urine on agar and bouillon showed colon bacilli. Aspirin discontinued and urotropin and sodium benzoate, ten grains of each, given every three hours. The next morning (16th day) chill, nausea, vomiting, and sharp shooting pain all over body, with frequent and painful urination. Temperature rapidly rose to 104.2°. Ice cap and alcohol sponge baths failed to reduce the temperature below 103.4°.

Mornings of 17th, 18th, 19th, and 20th days temperature was practically normal with an afternoon rise to 103°, 102°, 100.6° and 102°. During the next day temperature did not go above 100.8°, but patient was voiding every one or two hours in amounts from four to twelve ounces. Blood examination: Leucocytes 15,800 and polymorphs 89 per cent. Cystoscopic examination by Dr. A. T. Osgood. "Cystoscopy shows moderate subacute cystitis, diffuse over bladder wall, with marked swelling about right ureter mouth, from which cloudy fluid emerges. Left ureter mouth shares in diffuse cystitis, but shows no localized swelling. Both ureters were catheterized, urine obtained was light amber and cloudy from each. The urine from right ureter catheter was more turbid than that from left. Urine flowed from each at same rate and with normal intermissions. Part of turbidity may be due to phosphates or other normal constituents. Diagnosis must depend upon urine analysis and cultures."

Uranalysis: Light straw, acid, sp. gr. amount insufficient to determine, albumin a cloud, no sugar slight sediment. Microscopical examination shows motile bacilli with pus cells, leucocytes, and squamous cells.

Culture from both ureters show Gram negative bacilli (short) with morphology of colon bacilli. From the twentieth to the thirty-fourth day there were four acute exacerbations. The pain being referred to the right and left kidneys alternately with marked tenderness over the kidneys, and pain in the costovertebral angles on pressure. Towards the end of this time vomiting was almost constant with marked prostration. Blood examination: Leucocytes 13,600, polymorphs 81 per cent. The 31st day urotropin and sodium benzoate were discontinued and potassium citrate, grains 30, were given every four hours. At noon of 34th day, temperature 101.6°, and 100 million bacillus coli stock vaccine was given. This was followed by a marked reaction and temperature reached 104° in twelve hours. Temperature gradually fell to 100° by the morning of the 36th day, but by afternoon it again reached 103.2°. On the morning of the 38th day temperature came down to 98°, which was the lowest point reached in three weeks. The patient's general condition was much improved, micturition was frequent, but was relieved by reducing amount of potassium citrate to fifteen grains every four hours. However, temperature again reached 103° by afternoon, 100° by morning of 39th day, and 101.8° by afternoon. Urinalysis: Pale amber, alkaline, no albumin, no sugar, few red blood cells, and abundance of bacteria which on culture proved to be *Bacillus coli*. Blood examination: Leucocytes 11,600 and polymorphs 74 per cent. The afternoon of the 30th day, 100 million autogenous vaccine were given, and in four hours there was a rise in temperature of but four-tenth of a degree, and then the temperature gradually came to normal

on morning of 42d day, when a second 100 million of autogenous vaccine was given. This vaccine was continued in like dosage every third day until patient's discharge on the 60th day. From the 44th day, urotropin, grains 5, and potassium citrate, grains 10, every four hours were given, in addition to vaccines. Patient's convalescence was now quite rapid, although there was frequent micturition with tenderness in the right costovertebral angle. Two days before her discharge the urine was amber, acid, sp. gr. 1008, no albumin, no sugar, few red blood, and epithelial cells. Culture on agar and bouillon gave luxuriant growth in 48 hours of a short Gram negative bacillus with morphology of *Bacillus coli*. Five weeks after leaving hospital, and at her menstrual period, there was an acute exacerbation and 150 million stock vaccine was now given, with slight reaction and a daily recurrence of symptoms. At the end of a week 200 million stock vaccine was given and has been continued every week up to the present time. She has had but one other acute exacerbation, which was at a menstrual period, and she is now gaining in weight and general health, although there are at times pain in the kidneys and frequent and burning urination, and the urine has the macroscopical appearance of a bacilluria.

The following cases I report through the courtesy of Dr. Le Roy Broun, from his service at Woman's Hospital. Case IV. illustrates acute suppression of urine and might be easily mistaken for so-called acute ether nephritis.

Case IV. (5464).—Female, aged 20, admitted to Woman's Hospital, November 14, 1910, with a gonorrheal salpingo-oöphoritis of ten days' duration. Smear from cervix showed the gonococci. Urine light amber, acid, sp. gr. 1035, trace of albumin, and many pus cells. Temperature 100°, pulse 100, and respiration 24. After two weeks' treatment temperature and urine became normal.

December 8, 1910, abdominal salpingo-oöphorectomy by Dr. Broun. First twelve hours following operation patient secreted only one dram of urine and in the next twelve hours but six ounces. Urine cloudy, acid, sp. gr. 1025, trace of albumin, and blood cells. Patient was very restless, complaining of severe pain in abdomen and back and vomiting incessantly. Nausea and vomiting were persistent for the next four days, and at the end of this time the patient first retained nourishment by mouth. The urine had now gradually increased up to twenty-four ounces, plus some that was lost. The treatment used was the Murphy drip, hot application over kidneys, electric light treatment (Goldspoon), and nutrient enemata with sodium acetate added. Urine, light amber, acid, sp. gr. 1012, slight trace of albumin, blood and pus cells, but no casts. Culture from urine gave the colon bacillus and Gram positive cocci in clusters and chains. From the fifth day on the urine steadily increased in amount, although the temperature did not remain normal until three weeks after operation. Gonococci were absent in smear from cervix and a second culture from urine showed Gram negative bacilli resembling *Bacillus coli*.

The following case illustrates a staphylococcus infection and an acute *Bacillus coli communior* infection developing seventeen days after operation.

Case V. (5877).—Admitted to Woman's Hospital, March 3, 1911, with the following history: Female, age 36, vii-para. Normal confinement (midwife) five weeks ago, in bed fifteen days. Third week, post-partum, history of gonorrheal infection, and has been confined to bed for last two weeks. On admission temperature 99.6°, pulse 100, and respiration 48. Examination showed a tender subinvoluted uterus, double tubo-ovarian disease, and slight tenderness over left kidney. Urine cloudy, acid, sp. gr. 1012, small amount of albumin, no sugar, leucocytes, and few pus cells. Culture from urine showed staphylococci. Leucocytes 15,000, polymorphs 75 per cent. Von Pirquet test negative. Urotropin and sodium benzoate, āā grains 10, were given every three hours for next six days, in addition to symptomatic treatment.

March 9, 1911, operation by Dr. Broun, supravaginal hysterectomy, for septic uterus and double tubo-ovarian abscess. Culture and smear from tubes and ovaries negative. Twelve hours after operation catheterized specimen of urine was of amber color, cloudy, acid, small amount of albumin, large amount of pus cells, and hyaline casts. Culture from urine negative. Forty-eight hours after operation the patient developed acute dilatation of the stomach. Postoperative temperature never above 100°. Out of bed on fifteenth day, and making good convalescence.

Seventeenth day temperature 102.2°, rapid pulse, labored respiration, and severe sharp pain in left kidney. Urine, amber, cloudy, slightly acid, sp. gr. 1008, no albumin, no sugar, epithelial cells and leucocytes. Culture from urine, pure *Bacillus coli communior*. Transplant showed the same. Urotropin and sodium benzoate, āā grains 10, every three hours. Two days later culture from urine showed a few specimens of *Bacillus coli communior*. Nineteen days later, on discharge from hospital, culture from urine showed no growth.

The following case shows the spontaneous recovery from a *Bacillus coli* infection:

Case VI. (5940).—Female, age 23, ii-para, no previous illness. Admitted to Woman's Hospital, March 20, 1911. Diagnosis double pyosalpinx and left ovarian abscess. Leucocytes 12,000, polymorphs 86 per cent. Urine, amber, cloudy, acid, sp. gr. 1032, no albumin, no sugar, few leucocytes and epithelial cells. March 28, 1911, vaginal panhysterectomy by Dr. Broun. In forty-eight hours temperature 103°, pulse 130 and respiration 30, but at end of another twenty-four hours these symptoms had subsided. The fourth evening after operation she complained of severe pain in back and right lumbar region. Previous to this time patient was catheterized, but now began to void small amounts of urine every two to three hours. The next night unable to sleep because of frequent and painful urination. Voiding every thirty minutes to an hour and a half, in amounts from a dram to two ounces. A catheter was passed and no urine found in bladder. From this time until the tenth day after operation she complained of right lumbar pain and frequent urination, then these symptoms subsided spontaneously. No enlargement of the right kidney or evidence of pain on deep pressure.

The seventh day the urine was light amber, turbid, alkaline, sp. gr. 1025, no albumin, no sugar, amorphous urates and phosphates. A culture showed *Bacillus coli*. Two days later the symptoms subsided, urine amber, clear, acid, no albumin, no sugar and microscopical examination negative. A culture from urine still showed the *Bacillus coli*.

The following case demonstrates a focus of colon infection with *Bacillus coli* in the urine and no clinical or pathological evidence of urinary infection:

Case VII. (5537).—Mrs. E., age 37, admitted to Woman's Hospital, December 6, 1910. Temperature 100.6°, pulse 118, respiration 22. Leucocytes 15,200, polymorphs 79 per cent. The temperature ranged from 100.4° to 102°, and on third day leucocytes 16,900, polymorphs 82 per cent.

December 9, operation by Dr. Broun. Posterior colpotomy, clots and dark blood evacuated, followed by a profuse hemorrhage. Rapid median incision, which revealed a ruptured left ectopic pregnancy with active bleeding. Mass removed and hemorrhage controlled. For two weeks temperature in afternoon ranged between 100.4° and 102°. The twelfth day the abdominal wound broke down and a culture of the pus gave colon bacilli. Urine, amber, acid, sp. gr. 1025, no albumin, no sugar. Culture showed colon bacilli. There was no frequency nor burning of micturition, no tenderness or pain in kidney or bladder.

December 26, 40 million dead colon bacilli (stock vaccine) given; at end of five days 40 million more, and at end of another five days 76 million. Three days after second injection, temperature reached normal for first time in twenty-five days, and amount of abdominal discharge was less and healing stimulated. However, the urine gave a culture of colon bacillus thirty-two days after operation, although throughout there had been no symptoms of any urinary involvement.

The following case is reported through the courtesy of Dr. Dougal Bissell. It shows a primary focus of colon infection with a secondary urinary infection.

Case VIII. (5502).—Female, age 24, admitted to Woman's Hospital, November 25, 1910. For fifteen days severe pain in region of left kidney extending across the abdomen and around to the back. Tender mass in left kidney region, which *x*-ray examination showed to be encroaching upon the diaphragm, but the kidney was not made out. Urine, catheterized from bladder, amber, acid, no albumin, no sugar, few squamous and round celled epithelial cells, one cylindroid, and urea 12.5 grams per liter. Urine from left ureter amber, cloudy, acid, no albumin, no sugar, few leucocytes, red blood cells, hyaline and granular casts, and urea 18 grams per liter. Leucocytes 20,000, polymorphs 88 per cent. Von Pirquet test negative.

For the first week the patient was very restless and noisy and complained of severe pain in left lumbar region. Temperature 100° to 102° F. December 1, 1910, operation by Dr. Bissell. Through a lumbar incision, a hard exudative mass was found posterior to the left kidney and between kidney and descending colon. Further investigation was postponed as patient took anesthesia badly. Gauze was introduced down to the mass and incision partly closed. For the first twelve hours after operation the temperature remained below 100°, and the first two weeks ranged from 100° to 102°. On the fourth day there was severe pain in the left ear, followed in three days by moderate purulent discharge. No culture was made from this discharge. The seventeenth day there was a discharge of pus and small amount of urine from the lumbar incision. Culture made from this discharge showed *Bacillus coli*. Urine, amber, cloudy, acid, sp. gr. 1018, trace of albumin, blood, and epithelial cells. Culture from urine showed *Bacillus coli*. Two blood examinations failed to show the plasmodium of malaria and an examination of the sputum for tuberculosis was negative. Following a free discharge of pus, the temperature remained normal for nine days, but on December 26 the afternoon temperature reached 103°. Leucocytes 19,000, polymorphs 77 per cent. December 27, urine, light amber, acid, sp. gr. 1010, trace of albumin, no sugar, epithelial, pus, and blood cells. Urotropin was given in seven and one-half grain doses three times a day and at end of six days the temperature became normal; except for this there was no improvement in general condition. The convalescence was very tedious and the wound was discharging freely. January 17, 50,000,000 (stock) colon vaccines given, January 20, 50,000,000, and January 24, 75,000,000. There was very little local and no constitutional reaction, but the discharge from the wound became appreciably less and it healed more rapidly. February 3, 1911, urine, amber, acid, sp. gr. 1012, no albumin, no sugar, leucocytes. Patient was discharged, as the mass and tenderness in the left side had disappeared, the sinus had healed, and her convalescence was well established.

Summary.

B. coli infection of urinary tract in health.	2 cases
B. coli infection of urinary tract post-partum	2 cases
B. coli infection of urinary tract post-operative	14 cases
Total number	18 cases

Primary focus of B. coli infection of post-operative cases when not in urinary tract was as follows:

Infected ectopic gestation and abdominal wound	1 case
Appendix and pelvic abscess	1 case
Gall-bladder and carcinoma of stomach	1 case
Appendix	1 case
Pelvic abscess and tubal disease	1 case
Perinephritic abscess	1 case

In all these cases hematogenous rather than ascending infection seems the most likely explanation of the mode of entrance. The possible exception was the case of perinephritic abscess which ruptured directly into the urinary tract although there was some previous kidney involvement.

233 West Eighty-third Street.

EPITHELIA FOUND IN URINE, AND THEIR DIFFERENTIATION, AS AN AID TO CORRECT DIAGNOSIS.*

By A. T. GAILLARD, M. D.,

PHILADELPHIA, PA.

In approaching any subject of scientific interest and value, with a view to enlightenment, one naturally seeks first the authority who has made the most careful researches, and who has published in clear, concise language the result of his work. In a previous paper I pointed out that the opinions of most authorities on the subject of epithelia found in urine are of little value, neglecting as they do the vital and essential points necessary to a successful study of this branch of microscopy, and destroying one's confidence at the very beginning by the fatal assumption that clear and definite conclusions are beyond the reach of the pathologist. To any one beginning with this assumption a working knowledge of the subject in question is of course impossible. It is first necessary to accept as truths

*Read before the Fulton County (Ga.) Medical Society.

the results obtained by the best authority, and in this field of microscopy at least, the satisfaction of confirming them by personal observation will not be denied the student. Louis Heitzmann, in his work on "Urinary Analysis and Diagnosis," has made a complete and scientific record of the possibilities in diagnosis by a study of the epithelia found in urine, and their differentiation. There is no doubt whatever that any good microscopist can attain reasonable proficiency by careful study of this book alone. The results of his work are clearly set forth—one has only to accept these results as well-established truths, and errors in diagnosis will seldom occur.

I shall devote as short a time as possible to the description of the various epithelia derived from the genitourinary tract, as the chief aim of this paper is to enter a protest against the fallacious teaching that results along these lines cannot be accomplished when these results have been undoubtedly demonstrated thousands of times, and corroborated by clinical proof.

As the study of epithelia depends for success largely upon recognition of their comparative sizes, the same magnifying power must always be employed. Experience has shown that the best results are obtained from the use of a 1/6 objective, with a 1-inch eye-piece, which in most instruments magnifies about 450 times.

For convenience of description epithelia common to both sexes will be taken up first. These are epithelia from the uriniferous tubules, pelves, ureters, urethra, and bladder. In the bladder, epithelia of the flat or squamous variety from the superficial layers are found in small numbers in normal urine. When large, round, or cuboidal shapes, from the middle layers, are seen in moderate numbers, an inflammation of some kind is present, even if secondary to disease of some other part of the genitourinary tract. As a result of deep-seated inflammation, such as ulcerative cystitis, tumor of the bladder, etc., there appear epithelia from the deep layer, which are columnar in shape and larger than any others of this character except those from the deep layer of the vagina. These epithelia are invariably seen in deep-seated inflammation of the bladder and cannot be mistaken for any others.

Epithelia from the urethra are partly flat or squamous, somewhat smaller than those from the upper layers of the bladder, partly cuboidal and partly columnar; they present the same appearance in male and female, though more common and more abundant in the former.

Epithelia from the ureters are usually cuboidal, though sometimes columnar, are invariably about twice the diameter of the pus corpuscles in a given case, and cannot be distinguished from those of the prostate gland, which they exactly resemble. Those from the ureter, however, are usually seen in connection with kidney and pelvic epithelia, and as primary injury to the ureter is comparatively rare, the diagnosis offers little difficulty.

Epithelia from the pelvis are somewhat irregular in shape, sometimes almost spherical, sometimes lenticular or pear-shaped. They are distinctly smaller than those derived from the bladder, and if this difference in size is carefully noted, and if they are present in sufficient numbers to observe the peculiar distinctive shapes, the common error of mistaking them for those of bladder origin will be avoided.

Epithelia from the uriniferous tubules of the kidney are never present in normal urine, and their appearance is always indicative of a pathological condition in the kidney. It should be strongly emphasized here that the study of all epithelia is one of comparative size; unless this is borne in mind it is impossible to make the differentiation. The pus corpuscle is taken as the unit, so to speak, and though varying in size in different individuals, varies but little in a given specimen of urine.

Epithelia from the convoluted and narrow tubules are usually almost spherical, generally contain a nucleus, and are invariably about one-third larger in diameter than the pus corpuscle in a given case. Their presence in the urine, especially if accompanied by epithelia from the straight collecting tubules, which are columnar in shape, always denotes a pathological process, and it is possible to make a diagnosis of irritation of the kidney or a nephritis perhaps, even without the presence of albumin and casts. The condition may not be a severe one, but is none the less present; it may be due to the irritation caused by an excess of urinary salts, or the indigestion of irritating drugs, but on the other hand a true interstitial nephritis may exist without the constant presence of albumin and casts, and which can be diagnosed in no other way than by the recognition under the microscope of these epithelia. It certainly seems utter folly for any one to deny that the differentiation is possible, at least in this part of the genitourinary tract, for specimens obtained by the ureteral catheter have demonstrated beyond the shadow of a doubt that these epithelia, distinctive in shape and size and seen only in specimens so obtained, if kidney lesion exist, come from the kidney and only from the kidney. Any objections to such conclusive proof can be regarded only as hopelessly prejudiced.

Epithelia found in urine of the male are those from the urethra, prostate gland and its ducts, seminal vesicles, and the ejaculatory ducts. Those from the urethra have already been described as irregular and usually somewhat smaller than bladder epithelia, but in severe inflammations there appear irregular columnar or cylindrical shapes, usually the result of ulcerations tending to stricture formation.

Epithelia from the prostate gland are cuboidal in shape, twice the diameter of the pus corpuscle, and, as already stated, of similar shape and size to those shed by the ureters. This similarity does not constitute a difficulty in diagnosis, however, if one remembers that ureteral epithelia are usually seen in connection with those from the upper urinary tract. With the absence of epithelia from the kidney or pelvis of the kidney, and the appearance of cuboidal shapes twice the diameter of the pus corpuscle, particularly if accompanied by epithelia coming from the ducts of the prostate, the diagnosis is certain.

Epithelia from the seminal vesicles are more or less irregular in shape, about the size of those from the duct of the prostate, occasionally contain yellow pigment, and when seen in the urine with a moderate or large number of pus corpuscles are an evidence of inflammation, possibly suppuration in the seminal vesicles.

From the ejaculatory duct come long, narrow, columnar epithelia, sometimes ciliated, though the cilia may be broken off, delicate parallel rods showing at the point of cleavage. Their size makes them characteristic; confusion between them and those from the bladder is impossible, the former being

narrower. It is sometimes possible to make a diagnosis of hypertrophy of the prostate gland before the clinical symptoms are manifested. In such a condition the prostatic epithelia are filled with so-called endogenous new formations, a collection of pus corpuscles originating within the epithelium itself and caused by pressure of the enlarged organ. These same new formations are also seen in the bladder epithelia, as the result of pressure on the bladder wall.

It is also possible by the study of these epithelia to make a diagnosis of acute and chronic prostatitis, spermatocystitis, and abscess of the prostate gland. No one will deny the value of being able to determine the source of pus in the urine, and in most cases the diagnosis can be made plain by a study of the epithelia present with the pus. For example—in acute abscess of the prostate the clinical evidences are usually of sufficient prominence to make a diagnosis, but it is quite possible that pyo-nephrosis or a severe cystitis may be coexistent. In acute abscess of the prostate the features under the microscope are moderate numbers of red blood globules, a large number of pus corpuscles, epithelia from the prostate gland and its ducts, sometimes in groups, connective tissue shreds, and mucus. These features alone, with an absence of kidney epithelia, make the diagnosis positive, and exclude the possibility of renal or other complication. On the other hand, in cases where more than one organ is involved, the seat of the severer lesion can always be determined by the comparative number of epithelia present from the various diseased sources.

What has been said of the possibility of tracing the source of pus in the urine is equally true in cases of hemorrhage. Hemorrhage from the pelvis of the kidney due to calculus can be diagnosed, hemorrhage from the presence of malignant tumor of the bladder, or hemorrhage from any other part of the genitourinary tract may either be positively diagnosed, or at least valuable aid may be given the clinician by the microscopist. It is not denied that some cases present great difficulties, that repeated examinations may be necessary before a definite conclusion can be reached, that in a few cases no diagnosis is possible, but in the great majority of instances I maintain that a positive opinion as to the source of the hemorrhage can be given from the urinary examination alone.

Epithelia found in the urine of the female come from the vagina, the Bartholinian gland, cervix uteri, and mucosa uteri Those from the vagina are the largest epithelia seen in urine and are flat in shape from the upper layers, cuboidal from the middle, and columnar from the deep layer. Inflammations of the vagina usually result in the appearance of epithelia from the Bartholinian gland, which are similar in shape and size to those derived from the prostate and ureters, about twice the diameter of the pus corpuscle.

Epithelia from the cervix uteri are somewhat similar to urethral, but more inclined toward the columnar shape, and as a rule are readily distinguished, while those from the mucosa uteri are long and narrow, similar in appearance to those described as from the ejaculatory duct but smaller and with cilia more often present. When these peculiar formations are present, together with epithelia from the cervix, they are indicative of a catarrhal endometritis.

Chronic diseases of the genitourinary tract may be diagnosed by the appearance within the epithelium of fat globules, and their presence in small groups throughout the microscopic field. These are small, glistening, highly refractive, granules and globules, and their appearance in the urine is always an evidence of chronicity. It is by no means necessary to employ one of the stains for the detection of fat.

It is not claimed that the source of every epithelium seen in the urine can be located, some must always remain doubtful, but if they appear in sufficient numbers the great majority of a certain size and shape can be accurately assigned to their proper source. There is no doubt whatever that all the epithelia described can be differentiated and a positive diagnosis made, independently if need be of the clinical history. In this fact lies the chief claim to consideration for this work, the importance of detecting early pathological changes, particularly in the kidneys, where disease is often far advanced before appreciable clinical symptoms appear. Even when albumin is found the error is commonly made of promptly dismissing the possibility of an existing nephritis because casts are not present. Some physicians err on the other side in making a diagnosis of nephritis in all cases of albuminuria, regardless of the cause responsible for the condition. Too much stress cannot be laid upon the importance of careful and repeated examinations before the kidney function is declared impaired, but the balance of error certainly lies in the direction of too infrequent diagnosis. When red blood corpuscles, pus corpuscles, and epithelia from the uriniferous tubules in moderate numbers can be demonstrated in the urine the diagnosis of nephritis is justified, is in fact positive.

One of the arguments advanced by some pathologists against the views expressed by Heitzmann is that actual pathological specimens of epithelia, obtained by scraping, do not show the differences in size and shape described as existing in fresh urine. This is quite true of specimens obtained in this way, but if examined in situ, and without exposing them to this destructive process, the characteristic shapes and sizes are perfectly apparent. And it can hardly be denied that the ideal condition under which to study epithelia is in the fresh state as they appear in the urine, only recently detached from the mucous membrane. But the hardest argument to combat, because it is really no argument at all, is the one that assumes in general terms the impossibility of obtaining results by these methods, the flat refusal to accept results already accomplished, already firmly proven. In the face of such skepticism it is hard to fight. I maintain that this method of diagnosis is based on sound, logical, and scientific principles. By rigid processes of exclusion the epithelia originating in the genitourinary tract have been accurately assigned to the various mucous membranes of which they were originally a part. Is it not logical to assume when epithelia of a certain shape and size appear constantly in the urine in cases where the clinical history is not in doubt that they are desquamated as a result of inflammation in that particular organ? And when these epithelia are never found in other lesions, and never appear in normal urine, is it not reasonable to insist that they come from that organ alone, and are present as a result of some pathological process causing their detachment? I do not wish to be understood as decrying or belittling the work of the clinician; on the contrary it should be emphasized that labo-

ratory work is only a much-neglected aid to correct diagnosis in those cases where the clinical history is obscure, or where an early diagnosis is of value because of a lack of clinical symptoms. This much I am willing to concede, but I must protest most strongly against the assertion that a diagnosis cannot be reached by laboratory methods alone. I have recently seen arguments absolutely denying the value of all laboratory work in the diagnosis of nephritis unless unmistakable clinical symptoms can be demonstrated. The fact is entirely overlooked that a chronic interstitial nephritis may exist for years with no appreciable clinical evidences, and if such statements are allowed to go unchallenged the unfortunate patient is denied the benefit of an early diagnosis and must await clinical manifestations of anasarca, dyspnea, cardiac hypertrophy, arteriosclerosis, etc., or until an acute attack intervenes, and a sudden uremic coma ends his life. The insidious onset of chronic interstitial nephritis is too well known to need emphasis; the disease is common in middle-aged men apparently in robust health, and the diagnosis unfortunately is often delayed until little can be accomplished in the way of treatment. The mortality experienced by insurance companies in this class of risks is very heavy, because albumin is either absent in the urine or the slight trace present is overlooked by the examiner. And until microscopical examination of the urine is more widely insisted upon these losses will continue.

Recent Actuarial Statistics show a steadily increasing percentage of mortality from the degenerative diseases, between the ages of 40 and 60. With a more general appreciation of the value of urinary analysis conducted along the lines of this paper, the mortality now being charged up to diseases of the kidneys would soon show a decrease, instead of the present alarming increase.

In closing three conclusions may be drawn:

1. That all epithelia originating in the genito-urinary tract may be differentiated.

2. That the diagnosis made by the clinician can always be confirmed by microscopical examination of the urine after the methods described.

3. That valuable aid in making a diagnosis can always be given when the clinical symptoms are obscure or too vague to allow of a positive diagnosis.

415 Walnut Street.

ON THE USE OF A DEFINITE TEMPERATURE IN TREATING DISEASE AND THE DESTRUCTION OF THE GONOCOCCI.

By J. A. FULTON, M.D.,

ASTORIA, OREGON.

Since the dawn of the history of medicine, heat and cold have held a prominent place in therapeutics, and the universal use of one or the other, both by the laity as well as by the profession, is conclusive proof of their value. In watching the effect of these two measures and endeavoring to decide why it is that either is of benefit at any time, or in any particular condition, I have arrived at certain conclusions which appear to me to be of sufficient value to justify me in submitting them to the profession.

In the past it has been sufficient to direct that hot or cold applications be made, without designating how much heat or what degree of cold was to be maintained. In using any chemical for a germicide it is required that it be used in a certain definite strength. Both heat and cold are germicides if used in proper strengths, and it is as easy to regulate the strength of our applications of these agents as it is of the chemicals in common use.

It has seemed to me, as it has to others, that nature in an uncertain way makes an attempt to use heat as a germicide by increasing the temperature of the body when pathogenic germs have gained a foothold in the system. Like others, I have seen the benefit of a high fever; I have seen an ulcerating tuberculous breast heal rapidly after an attack of erysipelas accompanied with a prolonged high temperature; I have seen a well-developed case of pulmonary tuberculosis which was making rapid headway almost entirely relieved by a long and severe attack of typhoid fever; I have seen an epididymitis apparently cure a case of gonorrhea in a few days; I have seen an acute attack of gonorrheal rheumatism with a high fever surprisingly relieved in a few hours and every attack with high temperature was followed by a lull in the severest symptoms. I have therefore come to look upon fever as nature's attempt to destroy germs.

The laboratory has shown us that all pathogenic germs thrive best at about the normal temperature of the human body. When the temperature goes above or below this the growth of the germ is retarded. Increase this temperature still more and the growth is stopped. Increase or lower it still further and the germ is killed. This occurs out of the body, then why not in the body?

The skin and tissues underneath are poor conductors of heat or cold. Nevertheless, I have proven time and again that either heat or cold may be sent into the tissues through the skin for a considerable distance. The skin will stand a steady application of heat at about 120° F. without injury to the parts. I say "about" for the reason that the skin of one person may be more sensitive than another, and may not stand quite as much heat and may blister. I have found none, however, that will not stand 118° F. and some that will stand 123° F. applied steadily for some time. It is possible to heat clear through the abdominal wall of a person not too fat. Cold likewise may be made to penetrate quite deeply without damage to the parts. The essential thing to observe in the application is that the temperature be of a known and unvarying degree, and be kept constantly applied. The haphazard method of ordering hot or cold applications is not to be depended upon any more than would be the application of an antiseptic without regard being paid to the strength of the application made. In using the Bier method of treatment, after the constricting band has been applied, the part should be wrapped in an electric heating pad kept at a known temperature, and the part under treatment subjected to prolonged high temperature with a probability or rather almost a certainty of heating clear through the part. In applying a poultice to any part, it is wiser to cover the poultice with the electric heating pad and by this keep it at a steady and known temperature, instead of the present method of making applications which are hot one minute, cold the next. That such a method would be of benefit there can be no doubt. I have in my work demonstrated time and again that a heated bougie held within the urethra will raise the temperature of the skin outside along the urethra from five to eight degrees. A heated instrument kept within the rectum or vagina will heat clear through into

the adjoining cavities, showing that heat may be made to pass through living tissues and that a part may be heated to a temperature several degrees above the surrounding parts without injury. I have seen a chronic ulcer of the leg heal rapidly after a twenty-four-hour application of heat at about 118° F. I have seen an eczema of the leg heal after a twenty-four-hour application of heat, and I am convinced that any infected part, such as an infected finger, will be benefited by a prolonged application of heat.

In view of these facts, I am led to believe that the benefit received from the applications of heat or cold comes in some way through the destruction or the weakening of pathogenic germs—in some cases the complete destruction of them; in others, perhaps, through such an influence on them or the blood cells as to encourage the production of opsonins or to increase the activity of phagocytes, and in this way assist in the cure.

There are some pathogenic germs which will require such a degree of heat to destroy them as to be destructive to the tissues, although subjecting them to a prolonged temperature as high as the tissues will stand may retard their development and weaken them so that nature can more easily destroy them. The laboratory has shown that there are some germs which a comparatively low temperature will destroy, and the one most easily reached is the gonococcus. The gonococci can not endure a temperature above about 113° F. outside of the body. Will that temperature destroy them in the body? I believe that I have proven that a temperature a few degrees above this will.

The gonococcus is of low vitality, notwithstanding the disease produced by it is stubborn to treat. The reason for this is that the germs as soon as located begin to burrow beneath the epithelial layer of the mucous membrane and are thus soon in a position to defy the action of the various antiseptics and washes that simply pass over them, and which do not injure them or retard their growth in the least.

Now if heat at 120° F. will destroy them or weaken them, so that nature's phagocytes may cast them out, we have a safe and simple remedy at hand. And since heat may be depended upon to penetrate the crypts and follicles of the urethra, it should be possible to prevent any such a thing as latent gonorrhea.

As to the best method of applying heat or cold at a definite and controlled temperature to the urethra, I have found that a metal tube in which water is made to circulate at a known temperature and which is supplied with a thermometer at the point of inflow, and another one at the outflow, keeping one informed as to the exact temperature of the bougie all the time, is best. By connecting this to an insulated tank which would prevent the rapid loss of heat, we are provided with an instrument which enables us to apply heat or cold to the entire length of the urethra and to know all the time just what we are doing.

During the past three years I have treated quite a number of cases of gonorrhea by this method. All of the cases met with have not been treated by this method for various reasons. Cases in which the meatus was too small to admit the bougie I have treated by other methods. Cases in which the patients did not seem to have sufficient intelligence to justify me in expecting to see them return to report have been let go. I have, however, treated quite a number of cases and have convinced myself that gonorrhea may be aborted or cured in one week and possibly in one treatment.

In applying this treatment to an acute case of gonorrhea I first wash out the urethra with a physiological saline or a weak boracic acid solution; then instill a three or four per cent. solution of stovaine; have patient recline on a table or lounge; have the bougie and thermometers hang from a hook on an arm from a tripod so that the bougie will, when introduced, not cause any needless discomfort. Then the water at the desired temperature is allowed to flow through the bougie and out into a vessel placed alongside of the patient. It is best to introduce the bougie before starting the water running so as to allow of a gradual increase of heat which is not so apt to be painful. The thermometers will show the temperature of the water at the entrance and exit of the bougie and the amount of loss of heat through radiation while passing through the instrument. The loss will depend upon the rate of flow, but should not be more than one degree. Our object should be to keep the temperature as high as the patient can stand it, and never to allow it to fall below 119° F. This temperature should be maintained for from thirty minutes to one hour. When the séance is over it will be observed that the mucous membrane is slightly swollen and that there is a watery discharge formed around the bougie. For a few days the urethra may be swollen and tender and the entire organ may at times be swollen and sore. Bathing in cold water has promptly relieved this condition. I have been accustomed to prescribe a mild zinc acetate solution for injection and citrate of potassium internally. Whether or not this is of any benefit to the patient I do not know, but it keeps him busy. I have had patients get well under this treatment in one week after one application of the heat. After three applications on successive days I have had no acute case take longer than eighteen days for a cure. Have had one case of epididymitis develop and in one case with an already irritable bladder a cystitis follow the treatment. In neither case do I think the complication was due to the treatment, but developed in spite of the treatment. In one case, in which an epididymitis was well started, one application of the heated instrument seemed to check it at once. My experience has been mostly with acute cases, but I have treated a few chronic ones. I have seen a case of three months' standing get well in one week after one application of the heat. I believe the heat has enabled me to cure my chronic cases more promptly than in any other way.

I have treated one case only with low temperature. In this case I applied a bougie at 34° F. for forty-five minutes. I made one application. The discharge stopped in eighteen days. There was so much inconvenience connected with getting the temperature desired in the cold treatment that I devoted the rest of my time to hot application. I believe, however, that in cold we have an agent of great value if properly used.

So far I have done only pioneer work in this method of treating this disease. Owing to the small amount of material at hand I have not been able to determine several things which must necessarily be worked out in any new treatment. Just how high a temperature may be used without destruction of tissues is a question to be determined. Whether it is best to make only one application of heat in an acute case of gonorrhea, or whether

an application every day for three or four days is best, is to be determined only from experience. In fact there is much to be learned and unlearned before we may sift the true values out of any method of treating disease.

In closing I may repeat that heat or cold used in treating disease should be in definite strength. That heat or cold when properly applied does readily penetrate living tissues. That a bougie at 120° F. held in the urethra for a few minutes will raise the temperature of the skin out alongside from five to eight degrees. And finally that the benefit following the proper application of heat or cold is derived from the effect upon, the weakening of, or the destruction outright of the pathogenic germ causing the disease which is under treatment.

Like everything else not thoroughly tried in medical work, it will take time to prove its full value. Nevertheless I submit these ideas to the profession with a feeling that the correct and scientific use of heat or cold (used in definite and known strength) offers much of value to the profession and merits a more careful investigation.

BACTERINE TREATMENT IN PULMONARY TUBERCULOSIS.

By GEORGE SANDERS, E.L.M., M.D.

NEW YORK.

THE hypodermic injection of dead germ cultures, known as bacterines or vaccines, is establishing itself rapidly as a therapeutic agent. It has frequently proven most successful, and with more knowledge of its proper application in appropriate cases a therapy of great usefulness will be at our command.

In all infections we have to wait for the blood to make its antibodies to neutralize and rid the system of the toxins, and when this is delayed it may result in a long illness which may end fatally, but by the early use of the bacterines a stimulation of the blood elements to fight the infection takes place and so saves the tissues from the longer influence of toxins. To immunize against or combat internal infections will be the widest field of the bacterines.

In pulmonary tuberculosis we deal with an internal infection caused by the tubercle bacillus. However, the tubercle bacillus, alone, finding a vulnerable point in the tissues, may hardly produce any symptoms, and the patient may not be aware of any disease at all. It is held by many that an additional infection of one or more of the pus-forming organisms is the true cause of the more or less rapid downgrade progress of the disease, and the true cause of the breaking down of the tissues surrounding the tubercle, thereby causing cavities in the lungs. The chronicity of a case depends upon the degree of the secondary infection.

It is this secondary infection that causes rapid loss of weight and strength, fever, night sweats, loss of appetite, and mucopurulent and purulent expectoration. Tuberculin treatment in pulmonary tuberculosis has often proved harmful to the patient. Tuberculin treatment should not be undertaken when the patient is feverish, but in most cases of tuberculosis, and especially of the rapidly advancing type, fever is always present, considered from a point of 100° F. or above. Now, if by means of bacterine treatment we are able first to overcome this secondary infection to a greater or less extent, a patient then can be placed in a condition to receive any further treatment toward the direct eradication of the tubercle bacillus through the injection of tuberculin.

It is true that cases having reached an advanced stage in the disease may not or cannot be helped because of an exhaustion of the opsonins of the blood and of the great destruction of lung tissues.

In applying bacterine treatment to tuberculous patients, I was agreeably surprised in the results obtained. The following cases cited are not selected ones, but they are such, in succession, as came for treatment. These cases have not been treated long enough to show definite end results, but, owing to the benefits derived so far, their progress should stimulate general interest for the application of this therapeutic agent.

In using a combination of bacterines consisting of the various organisms that produce suppuration and other concurrent affections in tuberculosis we meet all likely indications.

The combination of bacterines used in the following cases consists of streptococcus, multivalent, 50,000,000; staphylococcus, multivalent, 500,000,000; communis coli, multivalent, 100,000,000; pneumococcus, 100,000,000, in each cubic centimeter. The dose injected is one-half this amount and thereafter increased or decreased according to the tolerance of the patient. A slight negative phase following an injection seems to be followed by better results than if none appears.

CASE I.—Mr. B., aged thirty-three years; occupation, salesman; came to me on October 12 of this year, with the following history: About four years ago he had a "cold" with fever, which kept him in bed for about six weeks. It was then discovered that he had pulmonary tuberculosis, as his sputum examination was positive. He then had a severe cough, night sweats, and loss of appetite, with rapid loss of weight and strength. Patient states that he weighed about 135 pounds when in good health and before this attack. He subsequently went to Liberty, N. Y., where he improved considerably and gained in weight. He had an hemoptysis about four times at that place. After about eighteen months he returned to New York City, where he since has remained. Since his return he had one slight hemorrhage from the lungs. During the summer months, he states, he loses in weight, but he gains in weight during the winter. His appetite has always been good, he has no sensation of fever, but he has occasional hectic flushes; he feels, as he states, "all in," and especially so on rainy and disagreeable days. He is unable to do any work or to take much exercise; he always takes medicine to keep him from coughing and to give him a night's rest.

Physical examination showed expansion of chest on inspiration more on the left side than on the right. Infraclavicular and supraclavicular spaces sunken on both sides, but more so on the right. Vocal fremitus distinct over right side. Dullness over right upper lobe. Over same part subcrepitant râles and rough bronchial breathing, also some bronchial breathing below. This young man has his heart on the right side of the chest. Pulse 118, temperature 100.6° F., weight 125 pounds. One-half cubic centimeter of the above named combined bacterine was injected, and instructions were given the patient as to his diet, fresh air, etc. He was instructed to stop his medicine.

October 14. Patient states that he felt a little feverish and that he had a headache soon after the injection. This all gradually disappeared in

a few hours. He sleeps now a little better, but otherwise feels as usual. Noticed a slight increase in cough. Pulse 100, temperature 98.6° F. Second injection of 0.8 c.c. of bacterines October 16. Patient states that he had no reaction from the previous injection. Yesterday having been a disagreeable day, he did not feel so well. He had a little night sweat the night before last, but none during the past night. Pulse 112, temperature 99.6° F. Third injection of 0.8 c.c. of combined bacterines. Examination of sputum showed the tubercle bacillus.

October 20. About one hour after the last injection the patient complained of a slight headache which lasted about an hour. He felt pretty well the past two days, considering that we had threatening weather and some rain. On such days he heretofore felt especially miserable and much weaker. He sleeps better lately. Pulse 114, temperature 99.8° F., weight 126½ pounds, a gain of 1½ pounds in one week. It has to be taken into consideration, however, that he always gained in winter, and one cannot assume that this gain was due altogether to the influence of the bacterines. I have no information as to whether he was gaining in weight before he started treatment. Fourth injection of ½ c.c.

October 24. Patient had a headache about one hour after the injection. This did not last long. He now sleeps well. Fifth injection of ½ c.c.

October 29. A slight malaise soon after the previous injection, which lasted about ten minutes. He sleeps well and feels generally a little better. Temperature 99.4° F., weight 127½ pounds. Sixth injection of ½ c.c.

November 1. There was no reaction from the last injection. Patient states that at times he coughs more than usual. Pulse 112, temperature 98.2° F. Seventh injection of 0.6 c.c.

November 5. There was no change. Patient seemed a little nervous to-day. Pulse 120, temperature 98.6° F., weight 128 pounds. Eighth injection of 0.5 c.c.

November 8. Patient states that he feels improved, and that he has noticed no hectic flushes since treatment and so far. Pulse 104, temperature 99.2° F. Ninth injection of only 0.2 c.c. (all I then had).

November 12. For the past two days he has not felt so well. The weather was and still is very disagreeable, with fog and rain. He, however, feels generally improved. Pulse 108, temperature 99.4° F., weight 130 pounds. I have not seen the patient since and I do not know what has become of him. He has been treated exactly one month and he has gained five pounds in that time.

The above case was one of a very chronic nature and what is noticed, (1) Improvement in sleep without medicines. (2) Changes in weather and rain did not affect him as much and sometimes not at all. (3) A steady gain in weight. (4) He felt a general improvement.

Case II.—Mrs. M., aged twenty-six years, married three years, one child born about ten months after marriage, and since then she does not feel well. Although always in good health prior to her confinement, she was often subject to "colds." A cough developed since the child was born. Last April she was examined by a physician and her case diagnosed as one of pulmonary tuberculosis. She was advised to leave town and she went to Sullivan County, N. Y. No improvement took place there and she soon returned here. Her average normal weight she stated was about 120 pounds. She is losing weight and strength rapidly and is getting worse. At the beginning she had some night sweats, but none lately. Cough is troublesome and mostly so in the mornings. Her appetite has been very poor for a long time and she takes no breakfast. Menstruation normal. Patient looks emaciated, chest narrow, with intercostal spaces prominent. Supra and infraclavicular spaces very much sunken, more so on the left side. Dullness on left upper chest. Subcrepitant and crepitant râles heard over both upper lobes. Pulse 100, temperature 98.6° F., weight 91 pounds. No injection of bacterines was made at this visit, October 22.

October 25. Pulse 114, temperature 98° F., weight 90 pounds. First injection of 0.5 c.c. of combined bacterines given and the customary instructions. Sputum is positive.

October 29. Patient states that she had a severe headache and malaise soon after the injection. She slept better the past night and she seems to have a better appetite. Pulse 98, temperature 98.6° F. Second injection of 0.5 c.c.

November 1. Again she had a severe headache and malaise soon after the injection. She had also a few attacks of weakness with feeling of faintness which, however, soon passed off. Pulse 96, temperature 97° F., weight 90 pounds. Third injection of only 0.3 c.c. given.

November 5. Patient states that the reaction after the last injection was very much less severe, and that on the day following she felt very well, better, in fact, than she had felt for a very long time. Pulse 82, temperature 98.6° F. Fourth injection of 0.3 c.c.

November 8. Patient had only a slight reaction. She feels well and looks more cheerful. Her appetite is improving. Pulse 90, temperature 98.2° F., weight 90 pounds. Fifth injection of 0.4 c.c.

November 12. There was a slight reaction. Patient states that she feels much improved and that her appetite is getting much better. She now takes some breakfast. Pulse 90, temperature 98.4° F., weight 90 pounds. Injected 0.35 c.c.

November 15. Patient had no reaction. She feels good. Seventh injection of 0.5 c.c. Pulse 102, weight 89 pounds. Patient states that she put on a lighter skirt to-day.

November 19. Patient had a very slight headache yesterday morning. Feels good, appetite much better. Pulse 90, temperature 97.4° F., taken by mouth after she had come in from the cold. Weight 89½ pounds. Eighth injection of 0.6 c.c.

November 22. Patient feels well. Pulse 100, temperature 99.4° F. (rectal). Ninth injection of 0.7 c.c.

November 26. Again patient states that she feels generally much improved. Pulse 94, temperature 98.6° F. (rectal), weight 90 pounds. Tenth injection of 0.8 c.c.

November 30. Patient had no reaction after the last increased dose. Her expression and general appearance are entirely different from when I first saw her. Pulse 95, temperature 98.6° F. (rectal), weight 90 pounds. Eleventh injection of 0.9 c.c.

December 6. On some mornings the patient complains of headaches, and rheumatic sensations, otherwise feels fine, as she expresses herself. Appetite very good. Twelfth injection of 0.65 c.c. Pulse 100, temperature 99° F. (rectal), weight 90 pounds.

December 10. Patient complains of a slight pain in the back and says that her menstrual period is a little ahead of time. Pulse 94, temperature 100° F. (rectal).

In this case again we have some direct improvements: (1) Improvement in appetite. (2) Improvement in general health. (3) Her appearance is not of a person who was very much under the influence of a wasting disease. No increase in weight is noticed so far, but she feels much stronger.

The dose of bacterines of 0.5 c.c. at the beginning brought on too much of a reaction, and when reduced most of the above changes began to show themselves.

A further report of the last case, together with new ones, will be made later. A fair trial of the bacterines given in tuberculous cases will, I hope, prove a step further in the therapy of the disease.

144 East Sixty-first Street.

A SMALL QUICKLY MADE STERILIZER.

By DOUGLAS H. STEWART, M.D.

NEW YORK.

Select any rather long, salt-mouth bottle having a good cork, rubber or other. Put into the bottom of this a heaping teaspoonful of borax, cover this with several pieces (2 or 3) of blotting paper of as large a size as will lie flat, pour in a teaspoonful of formalin, push down on this a layer of absorbent cotton to hold all in place, put in the article to be sterilized and shove the cork home.

Details such as wrapping an article in cotton to prevent shaking, or otherwise to protect it, may be left to the judgment of the reader. Broadly speaking, with the most ordinary care the contained should be as safe in this container as any ligature in its sealed tube.

Evidently the above is a description of a formaldehyde sterilizer and a most natural question is, is the amount of gas sufficient? A working formula for formalin states that five ounces (sprayed) will sterilize 1000 cu. ft. in ten hours. This strength would be about ½ per cent. of that in most bottles of the size required or (say) about two minims to a preserve jar—whereas, according to directions, a teaspoonful, spread out in surface exposure by the blotting paper, will stop any culture under its influence in ten minutes. Complete germicidal effects demand a safety margin, therefore I give twenty minutes. Practically the bottle remains shut for long periods and the instrument is exposed to the action of the germicide for the same length of time. The necessity of keeping the cork in place as much as possible need only be mentioned. Articles of a material affected by heat are here easily and safely cared for. An old-fashioned hypodermic syringe, with leather or rubber washers and plunger, is so difficult to sterilize without damage, that it is usually aseptic by accident only. Yet this method will put and mainain any such in a sterile condition. Any one employing vaccines and serums will appreciate the item of "individuality." That is to say, that several syringes and their needles may be placed in individual bottles, any one may be used p. r. n. without delay and then after being used may be carefully wiped, replaced, and resterilized. Whether the syringes are assembled, or their parts separated, or their needles in position, or not is all a matter of choice. Knives, needles, in fact, any instrument, may be submitted to the process; but towels, etc., should not be. It works too well on fabrics. It penetrates every fiber and the formaldehyde, being retained, renders gauze (for instance) an active irritant capable of producing a papular and erythematous dermatitis. Rust is a negligible condition. A new pair of scissors placed in such an apparatus in July, 1908, are still there. Once or twice they were covered with a sort of bloom, which was easily wiped off and the polished instrument remains unspotted and undimmed. The borax does not have to be replaced very often and the necessity for new formalin is shown by the curly and dry appearance of the blotting paper. A test by smell may be readily made. It is sure but harsh. And it is really unnecessary.

Summary.—The method suggested has its own field. It is portable, clean, and independent of temperature. It furnishes a receptacle which produces and maintains sterility. It works well in a room, on a pantry shelf or under a buggy seat. It is inexpensive and it is readily made.

128 West Eighty-sixth Street.

Significance of Typhoid Complications.—F. Klewitz points out that the real significance of the many different complications of typhoid fever was first realized only when this disease was regarded not as a local disease but as a general bacteriemia.—*Medizinische Klinik.*

Some Cases of Lesion of the Cauda Equina.—E. Cedrangolo presents a study of five cases of lesions of the cauda equina, which study has a bearing on the localization of such lesions within the spinal canal. Two tracts may be distinguished in the cauda equina; a medulloradicular, corresponding to the ninth and tenth dorsal and first and second lumbar vertebræ; and a radicular corresponding to the vertebræ from the second lumbar to the second sacral. If the first segment from the lowest be injured, the first radicular segment, there results an anesthesia and paralysis equal to that caused by a lesion of the medullary segment of the same number. For every clinical form of lesion of the cauda equina one must determine whether the lesion is of the root or of the medulloradicular segment. The conus is above the filum terminale and extends upward to the constriction of the lumbar swelling, that is, to the level of the fifth sacral root. In the conus are the centers of the bladder, of the rectal nerves, and of ejaculation and erection, and the center of the Achilles tendon reflex; here also start the motor fibers for the levator ani, the bulbocavernosus and ischiocavernosus, the detrusor and sphincter of the bladder, and the anal sphincter; finally the sensitive fibers for the bladder, rectum, perineum, scrotum, and sacrogluteal folds. Hence a lesion of the conus will cause disturbances of the sphincters: first, retention of urine and later incontinence of the bladder and rectum. In the genital sphere erection is completely abolished, and ejaculation is varied between partial and total absence of the orgasm. The cremaster and Achilles reflexes are abolished or enfeebled. Also there occurs anesthesia of penis, scrotum, perineum, or anus, according to the degree of the lesion. Above this segment is the epiconus, a lesion of which causes disturbances of the sacral plexus, and sensorymotor paralysis of the peronei or sciatic nerves. In every case one may localize the lesion by the presence of some of these characteristic symptoms. The study of the reflexes is important. Every skin zone is innervated by three roots, and anesthesia of any region must be caused by lesions of one root and also of the roots above and below it. The author analyzes his cases and shows how each set of symptoms may be referred to a definitely localized lesion of some part of the conus or epiconus.—*Giornale Internazionale delle Scienze Mediche.*

New York, February 24, 1912.

THE RATIONALE OF ACQUIRED TOLERANCE TO DRUGS.

THE manner in which the body protects itself from the action of foreign substances, more particularly from the action of virulent poisons, is a subject which has acquired considerable importance within recent years. That the organism possesses many different modes of disposing of its toxic invaders is pointed out in a paper on this subject by W. E. Dixon in the *Proceedings of the Royal Society*, November, 1911. One of these methods, as explained on the basis of Ehrlich's hypothesis, is the attraction of drugs to the protoplasmic molecule to which they are bound by certain atomic groupings. But the body possesses the power, in a simpler manner, of causing the synthesis of poisonous substances into relatively harmless ones. Phenol combines in the body with sulphates, forming phenol-sulphuric acid ($C_6H_5.O.SO_2.OH$); camphor unites with glycuronic acid; and salicylic acid combines with glycocoll, forming salicyluric acid.

The synthesis of the last named substance takes place in the kidney through the agency of a ferment. Carbolic acid and sodium sulphate have no chemical affinity for each other *in vitro*, the synthesis in the body taking place slowly, which would suggest that in this case also the union is the result of ferment action. Similarly chloral combines through the agency of a ferment, and almost entirely in the liver, with glycuronic acid to form urochloralic acid. In the case of the aromatic substances the protective synthetic mechanism has a certain teleological significance, for several of these substances are formed in the gastrointestinal canal and unless neutralized by the body would cause poisonous manifestations. In the case of alcohol the body meets the invasion up to a certain point by means of complete oxidation whose rate appears to vary in different individuals. The symptoms of alcoholic intoxication begin to appear as soon the blood contains from 0.1 to 0.2 per cent. of this substance. The apparent tolerance for alcohol manifested by those addicted to the use of this stimulant indicates that in these individuals the rate of oxidation is accelerated. This, however, is no proof that a true tolerance has been acquired.

The behavior of the body in the presence of alkaloids illustrates how real tolerance may be acquired. Morphine is split up into oxy-di-morphine, which is practically innocuous. It has been shown by Faust that, following repeated hypodermic injections of morphine into the dog, at first 70 per cent. of this alkaloid is excreted in the feces, but later only a trace of the poison is thus eliminated, while chemical examination of the tissues reveals the absence of any trace of the poison. These experiments proved that the tissues of the animal had acquired the power of destroying the poison. Similarly it has been shown by Heger and others that the tissue juices of the frog's liver have the power of completely destroying hyoscyamine. It has been shown by Cloetta that the natural tolerance of the rabbit to atropine is due to the animal's power of destroying this alkaloid, which process takes place in the liver. This normal power of destroying the alkaloid may be considerably increased as the result of daily injections of atropine for a period of several weeks.

In view of the widespread use of tobacco the question of how the body disposes of the nicotine that is absorbed is one of eminent practical importance. Dixon subjected this question to experimental investigation and found that a certain tolerance to nicotine can be acquired by those who use tobacco habitually. This substance is removed from the circulating blood by the liver cells, which through the agency of a ferment destroy the alkaloid, provided that this reaches the tissues slowly and in minute quantities, which is the case in ordinary tobacco smoking.

The manner in which the body acquires tolerance to certain inorganic substances is still veiled in obscurity. Examples of this tolerance are seen in the case of the gastrointestinal irritants, copper sulphate and zinc sulphate, and particularly in the case of arsenic. The arsenic eaters of Styria begin with doses of 0.02 to 0.03 gram of arsenous acid taken two or three times a week and finally attain the maximum dose of 0.452 gram, which they take without injurious effects. It is suggested by Dixon that the immunity to arsenic may be attributed to the combination of this substance with some organic compound, resulting in the formation of an indifferent body free from arsenical action. Of closely related interest is the tolerance to arsenic that may be acquired by the spirochetes of relapsing fever, by the *Treponema pallidum*, and by the trypanosomes. It has been shown that arsenic-fast trypanosomes are uninfluenced by arsenic *in vivo*, but *in vitro* they are even less resistant than ordinary trypanosomes. It would appear as if the trypanosome acquires the power of resisting the attack of arsenic by virtue of the presence of some substance in the body of the host which forms a non-toxic arsenical compound. Ehrlich's chemoreceptor hypothesis, in which he claims that the arsenic combines with the protoplasm of the trypanosome by means of certain atomic groupings, does not explain the experimentally demonstrated fact that these same trypanosomes are more sensitive to arsenic in the test-tube than ordinary trypanosomes. At any rate, the problem of arsenic tolerance, whether studied with reference to the protozoan or to the multicellular organism, is still a long way from solution.

STRIKES FOR GOOD HEALTH.

The enthusiastic work of certain social agencies which has been directed toward broad problems of social hygiene, as for instance in the antituberculosis movement and in the work of reducing infant mortality, has done much to arouse a general interest in the vital questions of sanitation. It may well be that the movements specified are but indications of the general trend of the times, but it is evident that the systematic education of the public by social and sanitary specialists backed up by enthusiastic laymen has made the people think more, not only of abstract sanitary movements, but of the personal problem of keeping well.

The labor unions are beginning to recognize the vital importance of the healthfulness of the conditions under which they work, as of course has been the case in the obviously dangerous trades from the start. They are coming to see the danger of such factors as bad air, overcrowding, poor lighting, etc. It is stated that within the past year the Cloak Makers Union of New York has successfully conducted twenty-eight "sanitary" strikes. These strikes have attracted very little public attention, "and yet," says *The Survey* (January 20, 1912), "they reflect a remarkable and dramatic forward movement in the great garment trades in New York, in which the workers, with the sanction and cooperation of the progressive employers, are attempting to secure through the force of collective action what neither self-interest on the part of some employers, nor the good opinion of the trade, nor State law and enforcement have been able hitherto to effect." Many of the strikes were against the cellar workrooms of the East Side, and the proprietors were forced to secure more healthful quarters. In one instance the proprietor had put up 6-ft. partitions within the shop, shutting off the light from the pressers and forcing them to work by artificial light. A number of these strikes were in protest against dangerous fire conditions. Such evidence of the awakening of a hygienic conscience among these workers of the city suggests to what extent this same influence must be making itself felt in the homes as well.

The tremendous influx of ignorant foreigners into this country makes the problem of maintaining healthful conditions a continued struggle, and the intelligent cooperation of the people among whom these foreigners settle, such as is suggested in these strikes for health among the garment makers of New York, must prove a powerful influence for good.

BALDNESS AND ITS TREATMENT.

The question of baldness and of the chances of its successful treatment is naturally one of absorbing interest. In all parts of the civilized world the tendency of hair to depart in an untimely manner from the heads of members of the rising generation is becoming more and more evident. The sight of a bald young man is so frequent as to give rise to no comment, and when a man reaches middle age he is almost expected to be bald to some extent.

Gottheil, in *Progressive Medicine* for September, 1911, deals with the matter at some length. He deprecates the tendency to treat the subject as a joke and discusses the ordinary forms of premature or senile alopecia, commonly associated with or following prevalent scalp affections known as seborrhea or eczema seborrhoicum. In recent years the custom of discarding head gear in the belief that thereby the growth of the hair will be stimulated or that its loss will be stayed, has been widely adopted. The fact is, however, pointed out that the skin and its appendages are peculiarly susceptible to the action of the sun's rays. Overindulgence in sun baths is prejudicial to the human organism, causing irritability and nervousness, cardiac and circulatory disturbances, and dermal lesions, sometimes of a serious nature. Well-known authorities on skin diseases state their belief, founded on long experience, that extended exposure to the rays of the sun finally causes marked baldness. Indeed, the effect of the *x*-rays is similar to that of the actinic rays of the sun in this respect. Yet the hatless habit must not be wholly condemned offhand. Undoubtedly it has its advantages, and it must be noted that savages in tropical climates, who wear little or no protection for the head, in the great majority of cases possess an abundant crop of hair. Furthermore, it is a moot question as to whether interference with the circulation caused by our modern tight-fitting hat bands is not as harmful to the growth of the hair as prolonged exposure to the actinic rays of the sun. Baldness is without doubt a disease of civilization and is one of the penalties attached to being an inhabitant of a progressive and cultured country. Perhaps the more civilized the country the more prevalent will baldness be, for extreme civilization infers a mode of life furthest removed from that of nature. Indeed, a lack of hair is almost synonymous with the acme of civilization and is one of the most annoying of the white man's burdens.

As for the treatment of baldness, few dermatologists are agreed on a uniform plan. It would seem that the most rational and most common sense remedial and preventive means, that is, when no definite disease is present, are to stimulate the tissues of the scalp and to increase the blood supply of the hair follicles. This may be best done by a second person. Brushing should be proceeded with vigorously and persistently for months, supplemented with the application of a suitable lotion. Even then no certain results can be guaranteed. Some check the loss of hair by these methods, others do not attain this much-desired end, and some apparently thereby hasten the defluvium capillorum.

CULTURE OF LIVING TISSUE CELLS.

That tissue cells might be made to proliferate outside the body in artificial media is, at first sight, a corollary from our knowledge of the survival of grafts under many circumstances. The perfected technique of the cultivation of minute unicellular organisms goes back for so many years that the prolonged failure of pathologists to cultivate body cells occasions wonder. It is more than possible that such attempts may have been made or at least

approximated in connection with the study of grafts and regeneration in man, to say nothing of work of this kind of zoologists and embryologists. That the growth of nerve fibers outside the body in coagulated lymph was the first step taken in this line of research seems only a step in advance of what we have long known of nerve grafts and regeneration. Why integrating phenomena are present in one experiment and absent in another has usually been explained in part by the presence or absence respectively of a suitable nutrient plasma. Hence, while the demonstration of the growth *in vitro* of tissue cells is startling enough, it is much less revolutionary than at first sight appears, save, of course, in its promise for the future.

In the *Berliner klinische Wochenschrift* for January 2 Hadda relates his personal experience with these cultivations. He came to the United States to obtain the technique and witnessed the demonstrations of Carrel, which he repeated on his return to Breslau. He endeavored to satisfy himself beyond all doubt that the proliferation which occurs is actually a growth and not representative of some irresponsible form of reproductive cell activity. There could be no doubt that growth *in vivo* was paralleled to a certain extent, the rate agreeing, for example, with that of cell growth and not with that of arbitrary cell proliferation. Although these tissue cells grow *in vitro*, we cannot as yet say that they become specifically differentiated from the embryonal stage, or that they show any other tendency to organize. The cultures consist of spindle shaped cells arranged in series and felted together about a common center. The next step in order would appear to be a research into the fate of cell cultures when introduced into the tissues of living animals.

Chemotherapy.

As is well known this term has become the familiar designation for that form of therapeutics which seeks to destroy living parasites in the tissues by the selective action of certain diffusible substances which are powerless to injure the tissues of the host. It is essential that the remedy shall act through the medium of the circulation. In all probability the great internal remedies, some of which have been in use for centuries, owe their power over acute diseases largely to the possession of chemotherapeutic properties. We refer here chiefly to quinine, mercury, iodine, salicylic acid, and arsenic, all of which have been used empirically. Atoxyl against a trypanosome disease was presumably the first rational application of this principle, the benefits being ascribed here to the arsenic component of the molecule. Salvarsan marked a great advance in the same direction. At a recent meeting of the Gesellschaft der Charité Aerzte, Berlin (*Berliner klinische Wochenschrift*, January 15), Morgenroth read a paper on the subject which we are considering. The trypanosome furnishes a good test object of a chemotherapeutic research, as various chemical substances are able to attack it in the tissues, and synthetic derivatives of quinine, notably ethylhydrocuprein, have been tested on both trypanosomes and malaria parasites, as well as on various pathogenic bacteria, especially in the pneumococcus infection of mice. More recently attempts have been made to form a synthetic which shall exhibit the power of salicylic acid over rheumatism, and thus far this property appears to be possessed in some degree by para and metaoxybenzoic acids. The latter has all the force of salicylic acid with great reduction of its toxicity.

Chorioepithelioma Malignum.

This neoplasm is not only of constantly increasing interest in its local manifestations, but its sphere of contact with other biological problems seems to be constantly broadening. Indistinguishable from the fetal trophoblast, it has given rise to a belief in some quarters that all cancer is due to the activation of latent trophoblastic cells in the organized tissues. The entrance into the blood of trophoblastic cells appears to give rise to such dissimilar conditions as gestation toxicosis and the visceral metastases of chorioepithelioma, which latter may even occur in the absence of a primary focus. At a meeting of the Medizinischer Verein of Greifswald (*Deutsche medizinische Wochenschrift*, December 7) Cohn called attention to two new features characterizing this neoplasm. He has noted that even in the most severe inoperable cases spontaneous resolution may occur. This he explains by the assumption that the tumor cells have entered the veins and set up thrombosis. In this way not only are metastases prevented but the primary growth suffers necrosis. That metastases occur is not due to the special malignancy of the growth, but rather to a merely accidental entrance of tumor cells into the circulation, doubtless of mechanical causation. Extirpation of the primary focus appears to favor metastasis.

News of the Week.

Feeble-Minded Children in New York.—The New York Society for the Prevention of Cruelty to Children has been investigating the subject of abnormal and feeble-minded children and has made a report which states that there are at the present time in New York approximately 7,000 distinctly feeble-minded children, or about 1 per cent. of the school population. This is in addition to an equal number of idiots and imbeciles, but does not include the borderline or morally defective children. Few of the children brought before the Children's Court are really vicious, about one-half are merely the victims of environment. The remainder are produced from the 10,000 mental or moral defectives who roam at large in the community without proper parental or medical supervision. Recent census statistics show that 30 per cent. of the feeble-minded children in the general population of the United States are the progeny of aliens or naturalized citizens, and from this it may be assumed that at least 3,000 of the 10,000 feeble-minded children in New York were brought here, or are the offspring of the 9,000,000 aliens who have come to this country in the past ten years. In view of these facts the committee making this report urges the enactment of legislation whereby children may be subjected to a preliminary examination as to their mental development, before being admitted to the schools and from time to time thereafter and whereby all children coming before the Children's Court may be subjected to a similar examination in proper cases. They furthermore urge the establishment of an institution for the care and treatment of this class of children and the enforcement of legisla-

tion preventing the future admission of such children with immigrant families.

National Movement for Mental Hygiene.—A meeting of the National Committee for Mental Hygiene was held on February 17 at the Hotel Manhattan in New York, when it was announced that an anonymous donor had given $50,000, which will be immediately available for the work of the committee, and another gift of $50,000 has been promised toward a permanent endowment fund as soon as $200,000 has been raised. The work of this organization will take the form of a systematic effort to improve conditions affecting the condition of the insane as well as the education of the same on the subject of mental disorders, their causes, prevention and cure. Dr. William Russell, superintendent of the Bloomingdale Hospital, is chairman of a committee to make a survey of the national field, and Dr. Thomas W. Salmon of the United States Public Health and Marine-Hospital Service has been granted a leave of absence in order that he may take charge of the active work of the survey. The officers elected at the meeting are: *President*, Dr. Lewellys F. Barker of Johns Hopkins University; *Vice-Presidents*, Dr. William H. Welch of Johns Hopkins University, Dr. Charles P. Bancroft, superintendent of the New Hampshire State Hospital, Concord, N. H.; *Treasurer*, Otto T. Bannard, President of the New York Trust Company.

State Hospitals for the Insane Overcrowded.—The report of the State Lunacy Commission, which was presented to the Legislature on February 14, showed that there were in the various institutions of the State 33,311 committed insane patients. Of this number 31,051 were confined in the State hospitals; of these 14,569 were men and 10,482 women. The total number of patients paroled during the year was 781. There were during the year 5,573 new cases requiring commitment, and 1,383 relapsed cases requiring recommitment. The capacity of the State institutions was exceeded by 3,043. During the year 1,628 patients were discharged as recovered. The deaths numbered 2,885, or 75 per 1,000, of those committed, being slightly in excess of those of 1910. The total disbursements for the year amounted to $7,931,660 and the amount collected from paying patients to $486,040, this being $86,000 in excess of the previous year. The commission again recommended that there be a single-headed commission instead of the present commission, consisting of three members. They also urged the speedy development of the new Mohansic State Hospital, the Creedmore Branch of the Long Island State Hospital, and the extension of the Ward's Island lease to fifty years.

English Birth Rate Lowest on Record.—The quarterly return of births just published in London states that the births registered in England and Wales during the fourth quarter of 1911 numbered 209,269, the lowest number recorded during any fourth quarter since the establishment of civil registration.

Meningitis in Houston and Galveston, Tex.—According to reports given out on February 11 there have been 74 cases of meningitis in Houston since January 1, of which 56 were within the city limits and the remainder in the surrounding country. There have been 24 deaths, only five of which have been white persons. Thus far six complete cures have been reported and as many more are said to be ready to be discharged as cured. Reports from Galveston state that there have been 16 cases of the disease in that city since the first of the year. Occasional new cases continue to be recorded in both cities.

Pneumonia in Chicago.—Pneumonia is unusually prevalent in Chicago. During the week ending February 12 there were 704 deaths in that city from all causes and of this number 178 were from pneumonia. There were 663 deaths for the corresponding week of 1911.

Reports of Typhoid Fever in Milwaukee Said To Be Exaggerated.—Dr. Frederick A. Kraft, Health Commissioner of Milwaukee, has come out with the statement that the accusations alleging that the Health Department has been negligent in protecting the water supply are unfounded as well as the statements creating the impression that there is an epidemic of typhoid fever in the city. According to the statistics of the Health Department there is less typhoid fever than usual in the city, there being but 93 cases at the present time; many of the cases reported as typhoid have been only diarrheal affections cured in from a week to ten days.

Smallpox in St. Johnsbury, Vt.—There is an outbreak of smallpox in St. Johnsbury, on account of which the schools have been closed indefinitely. There are ten cases in four families.

Typhoid Inquiry.—Health Commissioner Lederle has appointed a commission of physicians and sanitary experts to study the methods of the New York Health Department in handling typhoid fever and to suggest, if possible, improved methods. Among those present at the first meeting of this commission were Professors William T. Frederick of the Massachusetts Institute of Technology, George G. Whipple of Harvard, C. E. A. Winslow of the City College, Drs. John Winters Brannan, Alexander Lambert, and Herbert D. Pease, together with a number of representatives of the Health Department.

Proof of Inquiry from Pasteurized Milk Demanded.—A letter has been sent out signed by Nathan Straus which states that in spite of the well-considered policy of the public health service in recommending pasteurized milk it is repeatedly asserted that its use causes rickets, scurvy, and anemia, and thus people are frightened into exposing their children to milk-borne diseases. In order to bring this issue to an end Mr. Straus offers $1,000 for any case of scurvy, rickets, or anemia caused by feeding a baby with properly pasteurized milk. If any such case is alleged the determination of the facts will be left to Dr. Rupert Blue, Surgeon-General of the Public Health and Marine-Hospital Service; Dr. M. J. Rosenau, of the Department of Preventive Medicine, Harvard Medical School, and Dr. John F. Anderson, Director of the Hygienic Laboratory of the Marine-Hospital Service, or to any jury that they may choose.

New York Health Department Prepared to Test for Syphilis and Gonorrhea.—Announcement is made that the Research Laboratory of the Health Department is prepared to make the serodiagnostic test for syphilis and for gonorrhea. Apparatus and directions for drawing the blood may be had on application, and only glassware specially prepared by the Research Laboratory may be used. With the apparatus is sent also an outline for the history of the patient. Data obtained in connection with these cases will be for laboratory use only and not accessible to the public. As a rule these

tests will be made only for those patients who cannot afford to pay for an examination and only at the request of the physician in charge to whom reports will be sent. If so desired blood will be drawn at the Research Laboratory on Monday and Thursday between the hours of 10 and 12. The announcement contains the statement that a positive reaction is not obtained within six weeks to three months from the time of infection in syphilis, or within six weeks in cases of gonorrhea, and a negative reaction does not exclude the possibility of specific infection either before or after treatment. It is also stated that the ingestion of alcohol within twenty-four hours of the collection of the specimen of blood interferes with the accuracy of the test.

Presentation of a Portrait of Dr. Wyeth.—At the meeting of the New York Academy of Medicine on February 14, Dr. Simon Baruch, as chairman of the committee designated to procure a portrait of Dr. Wyeth, presented the portrait, which was painted J. Campbell Phillips. In making the presentation Dr. Baruch read letters from several contributors to the fund expressive of the high esteem in which Dr. Wyeth is held. The picture is to be placed in the gallery devoted to portraits of presidents of the New York Academy of Medicine.

Indiana State Board of Examiners Sues Healers.—Recently the Indiana State Board of Examiners filed suits against a number of "chiropractors," a sect of "healers" who practise after a course of study of only a few months, on the ground that they are practising the healing art without complying with the law. On the other hand, the chiropractors claim that they should be exempt from the provision of the law because their name is not contained in the statute.

Is Advertising a Bar to Medical License?—The question whether the fact that a physician advertises is a valid reason for the rejection of his application for a license to practise medicine in Minnesota has been submitted to the Attorney General. It is the basis of a complaint filed by Dr. Boyd Williams in an appeal from a recent action of the State Board in which he was denied a certificate to practise medicine because he had advertised for patients.

Owner of Medical College Sues State Board.—Dr. Waldo Briggs, owner of the College of Physicians and Surgeons of St. Louis, Mo., has filed a suit for $200,000 damages against the State Board of Health because the board ordered his college stricken from the accredited list of medical colleges.

State Medical Examiners Appointed.—Dr. Thomas McDavitt of St. Paul, Dr. John E. Campbell of South St. Paul, and Dr. A. G. Moffatt of Howard Lake have been appointed to the State Board of Medical Examiners of Minnesota.

Medical Reciprocity in Quebec.—A bill has been presented to the Legislature in session in Quebec the intention of which is to authorize the Roderick Act to become operative in Quebec. According to this law medical certificates will be recognized all over the Dominion, with the previous individual consent of each province.

Dinner for Dr. Finney.—A dinner was given Dr. John M. Finney by his associates in Baltimore as an expression of their pleasure over his decision to remain in Baltimore instead of accepting the presidency of Princeton University. About 300 physicians and surgeons attended and among the speakers were Drs. Patton, Hibben, Remsen, Torney, Robert Abbe, and Surgeon-General Stokes. It was announced that a fund of $10,000 had been raised to bring foreign lecturers to Johns Hopkins and to increase the knowledge of surgery, to be known as the Finney Fund.

New Appointments at University of Pennsylvania.—The following appointments have been announced for the medical department of the university: Dr. Edward Lodholz is to be assistant professor of physiology; Dr. W. N. F. Addison, assistant professor of normal histology; Dr. George H. Fetterolf, assistant professor of anatomy; Dr. L. A. Ryan, assistant professor of chemistry and toxicology.

Honor Pioneer Doctors.—The Boone County Medical Society give a banquet at Boone, Ia., on February 9 in honor of Dr. G. D. Rowe, who came to Boone in 1868, and Dr. J. H. Noyes, who came to Ogden in 1867, both of whom have been in continuous practice ever since.

Dr. Carl Von Noorden of Vienna has accepted the invitation of the New York Post-Graduate Medical School and Hospital to deliver a series of lectures on Metabolism in October, 1912.

Dr. Frederick G. Hallett, secretary of the examining board of the Royal Colleges of Physicians and Surgeons, has arrived in this country in response to the invitation of the Council on Medical Education of the American Medical Association to take part in the conference on medical education to be held in Chicago on February 26.

Dr. William M. Conant is to be the new head of the surgical department of Tufts Medical School, Boston, and Dr. William A. Brooks is to be his assistant.

Dr. Simon Flexner has sailed for Europe to be gone two months. He will lecture in London on a public health topic and in Edinburgh on the serum treatment of meningitis.

Dr. Simon Baruch of New York addressed the New Rochelle Medical Society by invitation on February 12 on the "General Aspects of Hydrotherapy."

Dr. C. S. Huffman of Columbia, Kas., has been nominated for Governor of Kansas.

Charitable Gifts.—The Tuberculosis Preventorium for Children at Farmingdale, N. J., has received $5,000 from Jacob H. Schiff, $1,000 from Mrs. Schiff, $1,000 from Eugene Meyer, Jr., and $500 from other contributors. There remains to be collected but $2,500 in order to complete the fund of $150,000 needed for the new buildings which have been planned.—The will of the late H. Edward Wendell of Philadelphia bequeaths the sum of $1,000 to the German Hospital of Philadelphia.—Under the will of Miss Margaret E. Mitchell of New York, Roosevelt Hospital is a beneficiary for the amount of $15,000 and the Presbyterian Hospital for $1,000.

Tuberculosis Hospital Completed.—The new building for tuberculosis patients at the City Hospital of Providence, R. I., is about completed and will be ready for occupancy on April 1. There will be accommodations for 57 patients.

Maternity Hospital Needed in Washington.—At the hearing on February 7, before the committee on public health of the Chamber of Commerce, opposition was expressed to the recommendations of the Board of Charities that appropriations be discontinued and Columbia Hospital abandoned. A governmental appropriation that would enable Columbia Hospital to continue its work was favored as there is no other free maternity hospital, sepa-

rate from a general hospital, in the city of Washington.

Tuberculosis Home for New York.—The tuberculosis infirmary of the Metropolitan Hospital on Blackwell's Island will increase its accommodations for tuberculosis patients by the erection of a new building adjoining the present structure on the north end of the island. The new building will be constructed of local stone and blue stone and will cost $180,000. The main features of the new structure will be four roof gardens and a solarium.

Addition to Tacoma Hospital.—A building which will provide handsome quarters for physicians is to be built in connection with the Northern Pacific Hospital at Tacoma, Wash. The estimated expense of construction is $8,000.

A Unique Historical Exhibition.—It is announced that an historical exhibition of rare and curious objects relating to medicine, chemistry, pharmacy, and the allied sciences will be held in London during the International Medical Congress in 1913. This exhibit is being organized under the direction of Henry S. Wellcome, the aim being to bring together a collection of historical objects illustrating the development of the art and science of healing from the most primitive times to the present day. It is anticipated that the exhibition will reveal many facts and will elucidate many obscure points in connection with the origins of various medicines, and in respect of the history of disease. It is also believed that it will bring to light many objects of historical interest hitherto known only to the possessors and their professional friends. The exhibition will bé strictly professional and scientific in character and will not be open to the general public. Mr. Wellcome asks for the cooperation of all those interested in such an exhibit and especially appeals to all those who possess objects of historical medical interest to render their assistance in making the project a success by loaning such objects to him.

The Medical School of Yale University will celebrate the centennial of its founding in 1913. The present class will be the largest to graduate from this school, there being 31 members.

The Macon County Medical Society, which met in Tuskegee, Ala., on February 2, elected the following officers: *President,* Dr. C. E. Williams of Notasulga; *Vice-President,* Dr. B. W. Boothe of Shorter; *Secretary-Treasurer,* Dr. C. Thompson of Tuskegee.

The Fox River Valley Medical Society, which met at Neenah, Wis., on February 4, elected the following officers: *President,* Dr. D. T. Phillips of Menominee, Mich.; *Vice-Presidents,* Dr. F. G. Connell of Oshkosh, and Dr. S. G. Todd of Neenah; *Secretary-Treasurer,* Dr. Webber Kelly of Green Bay.

The New York State Homeopathic Medical Society, which met in Albany, elected the following officers on February 14: *President,* Dr. Willis C. Clifford of Attica; *Vice-Presidents,* Drs. R. W. Sherwood of Syracuse, Walter C. Crump of New York, and W. H. Pierson of Brooklyn; *Secretary,* Dr. Bert B. Clark of New York; *Treasurer,* Dr. R. D. Howland of Elmira; *Censors,* Drs. Harry E. Keith of Yonkers, Louis Faust of Schenectady, H. W. Basoner of Ithaca, and Glen L. Bidwell of Rochester.

The Ramsey County Medical Association, which met in St. Paul on February 5, elected the following officers: *President,* Dr. T. W. Stumm; *Vice-President,* Dr. C. J. Meade; *Secretary and Treasurer,* Dr. C. E. Smith.

The Forrest County Medical Society, which met in Hattiesburg, Miss., on February 9, elected the following officers: *President,* Dr. L. B. Hudson; *Vice-President,* Dr. Fern Champenois; *Secretary and Treasurer,* Dr. J. J. Stevens; *Censor,* Dr. C. W. Bufkin.

The Twin City Medical Association, which met in Centralia, Wash., on February 5, elected the following officers: *President,* Dr. W. B. Hotchkiss of Chehalis; *Vice-President,* Dr. J. M. Sleicher of Chehalis; *Secretary and Treasurer,* Dr. Rush Banks of Centralia.

A New Quarantine Head.—The appointment of Dr. J. J. O'Connell of Brooklyn as Health Officer of the Port of New York was confirmed by the Senate on Monday of this week, the vote being 21 to 15.

Obituary Notes.—Dr. JOHN P. HECHT of Somerville, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1880, died suddenly of angina pectoris February 12, at the age of 54. He died at the Somerset Hospital after exposure in attending to an accident case. He was surgeon to the Somerset Hospital, local surgeon for the Central Railroad of New Jersey, member of the American Medical Association, Somerset County Medical Society, Academy of Medicine of Northern New Jersey, and permanent delegate to the Medical Society of New Jersey. He was always greatly interested in matters of hygiene, for a long time member of the Raritan Board of Health, the Somerset Antituberculosis Association, and President of the Physicians Association of Somerville.

Dr. CARSON HENRY BRITTON, a graduate of Toronto University Medical Faculty in 1885, died at his home in East Toronto after a long illness, on January 31.

Dr. HERMAN L. WICHMAN of St. Louis, Mo., died at his home January 23, at the age of sixty-nine.

Dr. WALDEMAR KOCH of Chicago, Ill., assistant professor of pharmacology at the University of Chicago, a nephew of Robert Koch, died at his home February 2, at the age of thirty-six years.

Dr. PHILIP FRANK of North Yakima, Wash., a graduate of the Kentucky School of Medicine, Louisville, in 1889, died on January 22, at the age of sixty-one years. He was formerly president of the State Board of Health.

Dr. J. D. SCANLON of Vancouver, a graduate of the medical department of the University of Oregon in 1901, died on January 23 of an overdose of chloroform.

Dr. C. A. STILES of Seville, Fla., died at his home January 23, at the age of seventy-eight. For many years he had practised in Atlanta, Ga.

Dr. EUGENE D. CHELLIS of Portland, Me., died at his home February 1 after a long illness.

Dr. CHARLES W. RENNICK of Gas City, Kan., a graduate of the University Medical College of Kansas City in 1895, died at his home January 27. He was 41 years of age.

Dr. J. MILLER MOORE, formerly of Rock Hill, N. C., was found dead in bed in New York on January 28. He was 40 years of age.

Dr. WILLIAM HENRY TALLMADGE, Jr., of New York, a graduate of Jefferson Medical College, Philadelphia, in 1905, died at his father's home in Stamford, Conn., on February 7, at the age of 34.

Dr. JOHN BACON COOLIDGE, formerly a prominent

dentist of Boston, died at the home of his daughter in Natick, Mass., on February 3, at the age of 91. He was instrumental in starting the Boston Dental College in 1867, which afterwards merged with Tuft's Dental College in 1807, and held a chair in the college for twenty-seven years. He was the first dentist to use nitrous oxide gas, having given a demonstration of the use of this anesthetic in 1864, and was a prolific inventor of dental instruments. For his work in this field he received a certificate of honor from the Belgium Anniversary Celebration in 1840.

Dr. Hampton Stokes of Carmi, Ill., died on February 1 at the age of 70 years.

Dr. William A. Cross died at Jenkintown, Pa., on January 28 at the age of 68 years. He was graduated from Miami Medical College in the class of 1872.

Dr. Arthur M. Walker of Gala, Va., died of apoplexy on January 31. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1880.

Dr. Frederick Strong Tabor of Spring Valley, Ill., a graduate of Rush Medical College, Chicago, in 1881, died of valvular heart disease on January 29, at the age of 62 years.

Dr. Warren E. Anderson died at his home in Pensacola, Fla., after a long illness, on February 1, at the age of 57. He was graduated from the Mobile Medical College in the class of 1882. He was formerly secretary of the Florida State Medical Society and a member of the State Board of Health.

Dr. Evans Gulla of Hamburg, Ala., a graduate of the Medical Department of the Tulane University of Louisiana in 1901, died at a sanatorium in Ohio, January 28.

Dr. Sidney S. Graber of New York City, a graduate of New York University Medical College in 1888, died at his home February 8. He was 51 years of age.

Dr. George W. Fitzpatrick of Kansas City, Mo., a graduate of Ohio Medical College, Columbus, in 1863, died at his home, February 1, at the age of 70 years.

Dr. E. G. Wilson of Athens, Ga., died in New Decatur of pneumonia. He was 74 years of age.

Dr. Thomas P. Coan, resident physician of the New York Foundling Hospital, died of pneumonia on February 3 at the Presbyterian Hospital. He was graduated from the Johns Hopkins Medical School in 1910.

Dr. Lewis Slocomb Horton of Brooklyn lost his life in a fire in the basement of his home on February 5. He was graduated from the College of Physicians and Surgeons, New York, in 1862, and retired a few years ago. He was 70 years of age.

Dr. Elmer E. Fuller of Plymouth, Mass., died on February 6 after a brief illness at the age of 40 years. He was graduated from the Hahnemann Medical College and Hospital in the class of 1893.

Dr. Eno Sander died at St. Luke's Hospital, St. Louis, Mo., on February 11, at the age of 90 years.

Dr. George Denison Wheedon, a graduate of the Albany Medical College in 1853, died at his home in Syracuse, N. Y., on February 14, aged 79. During the Civil War he was surgeon to the Tenth New York Cavalry.

Dr. James W. Moriarty of East Boston, Mass., a graduate of the Harvard Dental College, died on February 11 at the age of 45 years.

Dr. Ralph M. Mead of Brooklyn, N. Y., a graduate of the Long Island College Hospital in 1882, attending physician to the Seney Hospital and visiting physician at St. Joseph's Institute for Deaf Mutes, died of apoplexy February 16, at the age of 55.

Dr. Henry K. Whitford of Elgin, Ill., a graduate of Eclectic Medical Institute, Cincinnati, in 1861, one of the founders of the National Eclectic Society, died at his home February 17 at the age of 85.

Dr. Peter Wendt Brakeley of Dunellen, N. J., a graduate of the University of Pennsylvania in 1869, died at his home February 12.

Correspondence.

THE LATE PROFESSOR ALBARRAN

To the Editor of the Medical Record:

Sir:—Prof. Joachim Albarran, who died in France, January 18, after a lingering illness of three years, was one of the most conspicuous figures among the professors of the Paris School of Medicine, though one of the youngest. He was born in Sagua la Grande (Cuba) in May, 1869. He first studied medicine in Madrid, then went to Paris. In 1884 he headed a promotion of internes, a number of whom are now professors or chief physicians or surgeons in the Paris hospitals. In 1888 he entered the service of Professor Guyon in Necker Hospital and remained there for fourteen years as interne, chief of clinic and "agrégé" professor. From 1901 to 1906, he was chief of service in another hospital; in 1900 he was called to succeed Professor Guyon himself, but soon the strain of overwork began to tell on him. In 1908 the suspicion of tuberculosis became confirmed and later diabetes aggravated the condition.

Albarran's field of research covered everything in genitourinary diseases. A skilled surgeon, he was also a trained bacteriologist and a master in anatomopathology. His contributions to medical science are well known and too numerous to quote at length. Though his professorship was prematurely cut short, he leaves enough behind justly to rank near his old beloved teacher, Professor Guyon, who now survives him.

Paxton E. Gardner, M.D.

New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INSURANCE ACT—RENEWED FIGHTING, COLLEGES, ETC., INTERVENE—FURTHER REFERENDUM BY PRACTITIONER—MEDICAL ASSOCIATION OF LONDON, CLINICAL MEETING—OESOPHAGEAL STRICTURE AND OTHER CASES—PROHIBITED MOVEMENTS OF DIAPHRAGM IN CONSUMPTION—OBITUARY.

London, February 2, 1912.

Suddenly after a lull the fight about the Insurance Act has become more earnest. Opposition on the part of the Oddfellows and others outside is added to that inside the profession, but to the latter only can I refer. On Wednesday the Council of the British Medical Association met to settle a report to present to the representative meeting on February 20, also to consider an invitation to attend a conference with the Insurance Commissioners relating chiefly to the selection of medical members of the advisory committee. The Council declined

to attend such a conference until after the representative meeting.

Yesterday the Royal College of Surgeons had a council meeting at which a similar invitation to attend the conference was discussed and declined. The Royal College of Physicians and the Society of Apothecaries take the same course and the proposed conference is now postponed. A report of the committee appointed by the College of Surgeons to consider the position of fellows and members under the Act was received and considered. Council concluded that the administration of the medical benefits proposed by the act cannot be carried out with due regard to the welfare of the public and the profession and that no satisfactory arrangement can be reached without an amending act. They would be prepared to render assistance in the drafting of such act for the provision of amendments which are necessary to secure the cooperation of the profession. The standing committee of the college was instructed to communicate with other corporations with a view to united action. If the act has alarmed the profession into genuine union it has done it one good turn, and the fact that it has awakened the omniscient corporations to a sense of their duties might cover many blunders when they are corrected, as all are determined they shall be. It is hoped by many that a central council may be formed by the corporations to support the profession in the crisis, but others ask what is the general medical council but such a body, permanently organized, but which so far has accomplished nothing. If the B. M. A. rises to the occasion it may establish itself in a position analogous to the trades unions. It now wields a good deal of the powers of such unions, but it must certainly not shirk responsibility and its council must understand that the inner clique will no longer be tolerated. It seems a monstrous abuse of association that an elected committee should decline to submit itself to the request of its electors or to resign office.

The B. M. A. Reform Committee, as it still calls itself, is rapidly pushing its organization, has taken offices, appointed an executive or secretary, and a business manager. This week it has re-issued the manifesto published on January 11 and a letter asking members of the B. M. A. to support a resolution at the representative meeting to call on all to refuse to form panels or undertake any medical duties under the act until the six points are embodied in our amending act. Such an act they are preparing; eight clauses are decided on and very important is one substituting the General Medical Council for the insurance commissioners as the body to have power to remove a name from the panel—thus liberating the medical men from the control of lay persons, which has always been hated in the club system.

The six points insisted on are also the object of the pledge proposed by the *Practitioner*, which has secured 21,000 votes. The conductors of that journal have now taken a further step, proving that it is wrong for the council of the B. M. A. to pretend they can secure their points through the regulations. The *Practitioner* said no, and as the fact was questioned from a legal view, has obtained the opinion of three eminent counsel (Sir E. Clarke, K.C.; Mr. Danckwerts, K.C., and Mr. Stuart Bevan) on each of the six points. Copies of these opinions they are now sending to every member of the profession; I received one this morning. It is obvious that the six points are not guaranteed in the act, and consequently the profession is left entirely in the hands of the approved societies. The policy of the *Practitioner* is "No-service-whatsoever." If the B. M. A. at the representative meeting will adopt this policy, the *Practitioner* will intervene no further than to assist in any manner desired. If not "steps must be taken to secure the ultimate triumph of the no-service-whatsoever policy." As to remuneration it is clear from the counsels' opinions that the profession in each district is left to haggle with insurance committees, three-fifths of their members being appointed by approved societies. That is the old contract system by the old clubs in a new dress.

You will observe that the outside, or partly outside, movements—and the same is the case with others not mentioned—propose to work through the British Medical Association, which has an organization ready to hand. If its council will only get rid of the dominating influence which has brought it to this pass or, if unable to do so, will submit itself for re-election and let the members eliminate the offenders, the other organizations will leave it in possession of the field in the belief that the fight must end in victory.

The Medical Society of London had a clinical evening on the 22d ult. and some interesting cases were shown, among them a boy who, after a fright, began to have spasmodic movements of muscles which Dr. Frith called paramyoclonus multiplex. Contractions of the orbicularis palpebrarum were synchronous and very uncertain as to frequency, sometimes a number quickly following, at others rest for several minutes. These were just what one has been accustomed to call spasmodic tic. But other muscles had become affected in a similar way. In the triceps and supinator longus the movements were most constant. There was no spasticity of the limbs, no clonus, and the electric reaction of the muscles was normal. No change was noticed while the lad had been under observation (about 9 months).

Dr. Parkes Weber showed a case of edema of the right leg in a woman of 29 with no other abnormality. It began about two years ago at the foot and has gradually involved the whole limb. It disappears gradually if the patient keeps her bed but returns when she gets up again. Thyroid treatment had proved negative.

Dr. Weber also joined Mr. E. Michels in a case of mutiple polyps of the large intestine with toxemia symptoms in a girl of 17, who four or five years ago began to have attacks of diarrhea with occasional protrusion of a lump from the anus. On April 24, at the hospital, it was found that the mucous membrane of the rectum and sigmoid flexure was studded with soft, sessile, or pedunculated tumors. The diarrhea was continual and the urine had excess of indican. In May some of these seemed to have become gangrenous and a small one, which came away, consisted of glandular tubules, lined with columnar epithelium with interstitial fibrocellular connective tissue. On June 1 Mr. Michels did appendicostomy and the intestine was then regularly washed out through the opening. The toxemia and diarrhea seemed relieved, but so far the polyposis persists, though the patient feels better and has gained in weight. The opening is being kept patent. At one time a weak solution of protargol was used for the irrigation.

A case which you might be excused for calling

an accidental cure of esophageal stricture was shown by Mr. Howarth and Mr. Corner. It was a little girl who in June, 1908, being then 4 years old, was playing in the street and seen to be trying to vomit, was taken to Guy's hospital and a week later was admitted for stomatitis with ulceration, it being supposed that she had swallowed some corrosive. In August of the same year she was taken into St. Thomas' hospital for dysphagia of two months' duration. Under full anesthesia and with an esophagoscope bougies could only pass 8 in. from the teeth. Gastrostomy was done by Mr. Corner and in November the child went to an infirmary. After a time the stricture relaxed and a bougie could be passed; it was dilated and the operation wound allowed to close. She can now eat ordinary food. Just below the cricoid several white patches are seen in the esophageal wall, not projecting into the lumen which is not narrowed. Did the stricture split in dilating and the rapidly growing epithelium form grafts over the splits which show as discontinuous white patches?

At the previous meeting of this society Dr. Harrison Orton, who has paid much attention to *x*-rays in a paper on the diagnosis of phthisis by their help, said restricted movements of the diaphragm, first pointed out by Dr. Francis Williams, are now generally admitted to be a valuable indication especially if present in the early stage. Careful measurements were sometimes required to fix it and it was sometimes impossible to detect it. Possibly it was present in all cases at some period but might have passed by before the inspection. It was suggested that discrepancies of opinion were probably due to the fact that variations took place. These had been noticed to correspond with periods of activity of the disease and perhaps might illustrate nature's means of giving rest to an inflamed lung, for during activity the movements were restricted, generally in the lower part of the excursion. When the activity abated the diaphragm again took on its usual work and might actually do more, as if to compensate for the limitation. In some cases adhesions might account for limited movements but they could not explain all.

Mr. Hallett, secretary of our conjoint examining board, is on his way to Chicago, having been invited by the council of the American Medical Association on Medical Education to address the meeting on the methods adopted by our board of conducting examinations for licenses to practice. He will also collect information as to the standards of education and the range of curriculum required by universities on your side for medical degrees.

Dr. Abraham Colles, visitor of lunatics in the metropolitan district for the London Chancellor of Ireland, died suddenly on Monday at the age of 63. He was a Dublin student and took his M.D. in 1878. He practised here for several years but retired some time ago in consequence of cardiac disease.

At the service held in memory of Sir Henry Butlin in St. Andrew's Church, Wells street, the congregation looked like an assembly of medical men, so numerous were the many leaders of the profession who managed to be present. At the same hour another memorial service was held at the Church of St. Bartholomew's-the-Less for the convenience of the staff of his hospital and others who were unable to be present at St. Andrew's.

Lt.-Col. R. A. King Holmes, M.D., late of the Indian Medical Service, died on Tuesday in London. He studied in Dublin, Galway, and Belfast, graduated at the R. U. I. in 1866, M.D. 1870, took M.R.C.S. Eng., 1871, and joined the Indian Medical Service the next year. In 1875 we find him jail superintendent at Meerut. He was transferred to Lucknow in 1885 and was acting as inspector of prisons in 1892 with the rank of lieutenant-colonel. He retired in 1899.

Manchester has lost a zealous laryngologist by the death of Dr. E. S. Yonge, physician to the Throat hospital in that city and to the Crossley sanatorium. He was the author of the plan of treating hayfever by resection of the nasal nerve. He lately published a book on "Diseases of the Nose and Throat."

OUR LETTER FROM PARIS.

(From Our Special Correspondent)

GENERAL EFFECTS OF GREAT HEAT ON THE ORGANISM—DIABETIC COMA—HEMOLYSINS IN PATHOLOGY—DIURETICS—EPIDEMIOLOGY AND PROPHYLAXIS IN CEREBROSPINAL MENINGITIS IN THE ARMY—PATHOGENY AND TREATMENT OF PUERPERAL ECLAMPSIA—THE FUTURE OF PREMATURE INFANTS—TREATMENT OF GENITAL DEVIATIONS AND PROLAPSUS—DEATH OF DR. AUFRET.

PARIS, January 15, 1912.

MAURICE DE FLEURY, at the Academy of Medicine, presented a study of the effects of great heat on the general organism. Gastrointestinal troubles in adults have assumed especial importance by reason of the abnormally high temperature of August and September last. There were numerous cases of cholerine, dysenteric enteritis, appendicitis, and paratyphoid fever, and many of the patients attacked still suffer from the effects of these diseases. The principal mechanism in the production of these diseases is the increased virulence of the pathogenic bacteria contained in the organism under the influence of a hyperthermal atmosphere. Great heat also acts on foodstuffs of animal origin, the toxicity of which is increased. Lastly, great heat produces an almost entire substitution of perspiration for the urinary function. Under the influence of external heat perspiration increases greatly in amount and the urine becomes less. Now the sweat eliminates much less toxins than the urine. The result of these factors combined is a continued hepatic congestion. It is only by a careful hygienic and therapeutic course that we can avoid serious accidents. Meat, milk, and eggs should be taken only in small quantities; drinking at mealtime should be stopped, and much water should be drunk in the intervals of digestion.

The twelfth French Congress of Medicine was held at Lyons, October 22-25, 1911. The first question of interest was diabetic coma. Lépine gave a detailed history of the different phases passed in reaching diabetic coma. The author believes that we are still far from knowing all the elements which unite to cause acetonemia and diabetic coma. The treatment of diabetic coma by bicarbonate of soda appears to be useful only as a preventive.

The second question discussed was the rôle of the hemolysins in pathology. Georges Guillain, Troisier, and Nole presented papers.

The third subject was diuretics, on which Mayor of Geneva read a paper on the mechanism of urinary secretion. It is not the increase of blood pressure, but the acceleration of the blood current which increases diuresis. Ligature of the renal

vein stops all diuresis, although it increases pressure. Diuresis is caused by certain selective medicines: digitalis, which acts by raising the general arterial tension with temporary persistence of the permeability of the renal arteries; caffeine has an action on the heart and vessels analogous to that of digitalis: theobromine causes a diuresis tardily established and slowly passing away.

Pic of Lyons thinks that among these medicaments we should place borage, juniper, dandelion, wild cherry (?), couchgrass, maize, and uva ursi. In all these plants there are diuretic principles which often have an irritant action on the kidney, but are so diluted that their action is slight. Among salines are chloride of calcium, in doses of 0.70 centigrams to 2 grams, which appear to have a marked diuretic action.

Arnozan criticises the phrase often repeated that "water is the best diuretic." In reality in persons who have edema, water can only cause oliguria. In certain patients rest in bed has no favorable action on diuresis. The dechlorated régime is the weapon of choice against renal dropsies.

The fourth question under discussion was the epidemiology and prophylaxis of cerebrospinal meningitis in the army. Rouget thinks that cerebrospinal meningitis is a disease of all the year except the summer. We note the disappearance of the disease in the spring. Dampness and cold have a predisposing effect. Dissemination of the disease takes place almost entirely by germ carriers, who easily transmit this terrible affection to their surroundings. All those who can be proved to be contaminated should each day have the nose, mouth, and pharynx disinfected. The diagnosis of cerebrospinal meningitis should be made from the finding of a cerebrospinal fluid that is turbid or purulent on puncture, and on the presence in the fluid of the pathogenic agent, the meningococcus.

The Obstetrical Society of Paris held its fourteenth annual session in October, 1911. The first question considered was the pathogeny and treatment of puerperal eclampsia. The pathogenesis of eclampsia was treated by Bar. Lesions of the liver and kidney play an important rôle as causes of eclampsia. Arterial hypertension should be considered a symptom of great importance in the pathogeny of puerperal eclampsia, capable of determining grave symptoms and lesions. The treatment of puerperal eclampsia was considered by Commandeur of Lyon. This treatment should be above all prophylactic. The treatment of the convulsions should be a large venesection of 1,000 to 1,500 grams. This will remove a great part of the poisons. The obstetrical treatment is rapid delivery.

The second question was the future of premature infants. Wallich and Fruhinsholz read papers. There is no doubt that many premature infants who have grown to adult life give every satisfaction with reference to their physical development and intellectual caliber; on the other hand, there are others who show various degenerations, and these degenerations appear especially in relation to the degree of prematurity and the violence of the traumatism at birth.

The third question was the treatment of genital deviations and prolapse. Doleris and Potocki presented papers. The surgical treatment of genital displacements should consist in reducing the uterus to its normal position and maintaining it there without lessening its mobility or changing its relations and anatomical position. The treatment of genital prolapse should be surgical. Abdominal hysteropexy with shortening of the round ligaments will assist when there are no perineal tears. When there is vaginal prolapse and cystocele we should have recourse to colpoperineorrhaphy and suture of the elevators, completed by anterior colporrhaphy, and if need be by amputation of the cervix.

Dr. Aufret, a member of the Academy of Medicine, is dead. He entered the service of the navy as surgeon, and was soon called to the school at Brest, where he taught successively anatomy, operative and clinical surgery. He was made director of the Sanitary Service, then inspector-general, and was called later to be president of the Council of Sanitation at Paris. He made important studies of diverticula of the intestine, prolapse of the intestines, and traumatic lesions of the ureters. These works amply justify the place which he occupied in the Academy of Medicine.

Progress of Medical Science.

Boston Medical and Surgical Journal.

The Responsibility of the Medical Profession for the Early Diagnosis and Prompt Treatment of Pulmonary Tuberculosis. J. B. Hawes, 2d.

The Influence of Race on the Prevalence of Tuberculosis. F. P. McCarthy.

Further Observations on the Fly Problem at the Worcester State Hospital, Massachusetts, 1911. S. T. Orton.

The Inefficiency of the Ordinary Bed Rest. Its Correction with a Thigh Support. L. T. Brown.

Early Diagnosis and Treatment of Pulmonary Tuberculosis.—J. B. Hawes, 2d, states that every patient in whom there is the slightest suspicion of pulmonary trouble should receive a routine physical examination, during which he should be stripped to the waist. Examination of the sputum should be a part of this routine. A "hemorrhage" should be considered as definitely indicating consumption unless there is clear evidence to the contrary, which there practically never is. The early diagnosis should be made long before bacilli appear in the sputum. One should place more stress upon the patient himself and his history and less upon his lungs. In every doubtful case the patient should keep a record of his temperature and pulse, taken at the hours of 8, 12, 4 and 8, and should report in a week.

Race and Tuberculosis.—F. P. McCarthy notes that a definite resistance has been acquired by certain races as a result of contact with tuberculosis over a long period of time, brought about by urbanization. The Indian and negro races have acquired as yet very slight resistance against the disease and preventive measures are practically the only means of stemming the mortality. The present high mortality rate among the Irish can be brought to a considerably lower level by the educational and preventive measures now in vogue. In the fight against the disease it may be possible to raise the resisting power of a race against tuberculosis. The relative low mortality among the Jewish people contrasts with the high rate among the aboriginal races.

The Fly Problem.—S. T. Orton describes the measures that have been taken at the Worcester State Hospital to abate the fly nuisance.

Bed Rest and Thigh Support.—L. T. Brown has devised a thigh support by means of which, no matter at what angle a bed rest or pillows may be put, there will be something under the thighs and below the buttocks to prevent any sliding downward and at the same time to give a comfortable rest for the knees and legs.

Alcohol and the Soldier.—L. L. Seaman makes a plea for the restoration of the canteen.

Cancer of Rectum and Lower Sigmoid.—By M. F. Porter. (See MEDICAL RECORD, January 13, 1912, page 87.)

An Atypical Case of Hyperthyroidism.—J. S. Horsley and B. M. Roseboro report a case of hyperthyroidism complicated by chronic appendicitis, retroversion of the uterus and a bilateral cervical tear.

Purpura Hæmorrhagica.—J. M. Wallheld reports a case of this condition.

The Salvation of the Consumptive.—C. P. Wertenbaker advocates the establishment of farm sanatoria, where tuberculous patients can receive care and treatment.

Vaccine Therapy in Diseases of the Ear, Nose and Throat.—V. Dabney states that in acute and subacute otitis media, stubborn, slowly healing sinuses following the mastoid operations, all forms of tonsillar infection and furunculosis of the auditory canal vaccines will surely abbreviate convalescence. Aside from preventing unnecessarily prolonged suffering, no mean consideration, this shortening of the duration of disease tends to prevent the familiar consequences of prolonged suppuration in the ear, such as deafness, great inconvenience, loss of time at work, expense, and even death.

Perforation of Gravid Uterus.—S. Wiener reports a case of this condition and discusses its diagnosis and treatment. The course that should be pursued as soon as perforation of the uterus is recognized is as follows: All further manipulation should cease, intrauterine irrigation should be dispensed with; the uterus and vagina should be packed; the patient placed in the Fowler position, and further developments awaited. Barring peritoneal infection, the majority of cases will show no further ill effects. If the uterus has not yet been completely emptied, this may be undertaken at a future time. However, if the accident has not been at once recognized, if there has been intraperitoneal manipulation with the curette or placental forceps, or if omentum or intestine has actually been drawn down into the vagina an exploratory laparotomy is urgently indicated. This should be performed just as soon as proper preparations can be made. A few hours may decide the question of the life or death of the patient. To await the development of active symptoms of peritonitis or the collapse supervening upon intraabdominal hemorrhage may turn the scale in favor of a fatal issue. The exact method of procedure after opening the abdomen must be determined by the conditions met with.

Pyosalpinx.—H. A. Duncan reports a series of 200 cases of this condition and notes that 0.45 per cent. of the patients were unsexed just before or at the beginning of their reproductive period of life. The direct cause of the pus tube is one of the most interesting of the phases in this series of cases. Of the 200 cases, fifty-six were due to infection by the gonococcus, fifty-six were due to infection following abortion; twenty-eight were due to infection following childbirth; fifteen were due to infection traveling from a purulent appendix; six were due to the tubercle bacillus; six were due to infection following dilatation and curettement done outside the hospital, and in thirty-three the direct cause could not be obtained.

Tumor of the Brain.—H. Climenko reports the case of a laborer 43 years old in whom a glioma existed for a considerable time in a functionally important area of the brain without giving any discomfort to the patient. When the symptoms made themselves apparent, they were of such rapid onset as to simulate an acute disease. The tumor was successfully removed.

Insanity in Children.—C. Holmes states that the anatomically unstable nerve centers of the vigorous, growing child offer a vulnerable field on which the maladjustments and abuses of a crowded, hustling city life may do irreparable damage. The ability to recognize the abnormal from the normal mental excitement, to appreciate that a certain form of unrest is developing as a direct result of distressing bodily or home conditions, to decide whether or not the child's conduct is due to his being fundamentally defective, to recognize the excitement of fatigue from overstudy—these are some of the things which should constitute the equipment of prophylactic workers in the homes and in the schools. Exceptional opportunities for the observation of incipient mental diseases, especially among children, are furnished by every large general hospital, but unless the hospital is equipped with special wards, specially trained nurses, and medical men for the care of such patients, these cases commonly pass through unnoticed.

Legal Powers of Health Departments.—W. A. Evans states that all health work is based on police power; to meet the unusual conditions the police-power laws must conform to certain legal standards. First, the condition which is sought to be met must be important. Second, the remedy proposed must be reasonably adequate to meet the demands and provision must be made for advancing standards in health legislation. Health laws and ordinances must be reasonable, taking into account the individual rights, which must be necessarily overswept at times, and must be guarded by giving due notice of what is necessary to be done. The wishes of the general public must rule and the mass must be protected regardless of the ordinary machinery devised to fit the usual conditions.

Nitrous Oxide and Oxygen Anesthesia.—F. Allen notes that writers quoting statistics designed to show the safety of gas and oxygen anesthesia should carefully separate the brief administrations of dentistry and minor surgery from the prolonged administrations of major surgery. Anesthetic deaths occurring during the use of nitrous oxide and oxygen in major surgery are not uncommon. There are at the present time not enough statistics as to the safety of nitrous oxide and oxygen in major surgery to show that it is as safe as ether or chloroform. In order to insure a maximum of safety, gas and oxygen should not be administered except by a skilled anesthetist equipped with the best available apparatus, and patients should receive preliminary hypodermic medication. In estimating the freedom from after-effects of gas and oxygen anesthesia in major surgery, careful distinction must be made between patients receiving gas and oxygen

only and those receiving gas and oxygen and "just a little ether." When given with large amounts of ether, gas and oxygen has only a slight advantage over the nitrous oxide ether sequence properly administered by the closed method.

Renal Tuberculosis.—W. F. Braasch, from an analysis of 283 cases of renal tuberculosis finds that there is a noticeable preponderance of males, in that they constituted 61 per cent., or almost two-thirds of the total number of cases. Although renal tuberculosis is generally considered as being confined largely to the young adult, 20 per cent. of the patients in the series were above 40 years of age. Hematuria was found to be present in 60 per cent. of the cases. Hematuria occurred about twice as often in the male as in the female. Bladder irritability in 80 per cent., renal pain either alone or coincidental with bladder irritability in 25 per cent., and hematuria in 6 per cent. of the cases are primary symptoms. Renal tumor was palpable in but 20 per cent. of the cases. Operative mortality is a negligible factor in nephrectomy for renal tuberculosis. One can expect a permanent cure in fully 75 per cent. of patients operated on. On the other hand, if otherwise treated, fully 90 per cent. must eventually succumb to the infection and in taking the small chance for such a cure the risk of infecting the bladder or infection of other foci is greatly increased.

Mouth Diseases.—E. S. Talbot reports cases of gonorrheal stomatitis and spirilla infection of the mouth.

Prophylaxis of Meningitis.—H. D. King states that nearly one-fourth of all individuals of the infected locality may be carriers of the disease without apparently showing any serious symptoms. Only occasionally do they present signs of a nasopharyngitis or slight meningococcal infection. There are some persons who probably carry the germs permanently and perpetuate the disease. Up to the present there has been no absolutely efficacious means of causing the disappearance of the germs in the carriers, but the rigid observance of certain precautions would limit the extent and severity of epidemics. The first essentials for this are: (1) The earnest cooperation between the people and the health authorities in enforcement of all necessary health regulations. (2) The detection and isolation of healthy germ carriers. (3) Efforts toward rendering them harmless.

Traumatism and Heart Disease.—By J. C. Wilson.

(See page 385.)

Salvarsan in Pernicious Anemia.—V. Friedlander reports a typical case of pernicious anemia in which, following an injection of 0.3 gram of salvarsan and then the injection of one grain of cacodylate of iron on alternate days until twenty-seven doses had been given, the condition rapidly improved.

Hormones.—C. D. Aaron concludes from his observations that the peristaltic hormone treatment of constipation provides a new and very promising method.

Cardiac Syphilis.—A. S. Warthin concludes that focal or diffuse fatty degeneration of the myocardium may be associated with the presence of numerous spirochetes of syphilis without reaction on the part of the interstitial tissues. Such changes probably represent a very acute or mild (latent) infection. It occurs very frequently in congenital syphilis. Calcification or fibroid change may follow the parenchymatous change without a definite interstitial inflammatory reaction. In such areas the spirochetes are few in number or have entirely disappeared, according to the stage of the secondary process.

The Lancet.

February 3, 1912

Medicolegal Aspects of Paresis.—Sir George H. Savage states that brutal assaults are frequently made by individuals who are in the early stages of general paralysis. Another early symptom is sexual excess. Adultery is common among these patients, as are likewise assaults on children and indecent exposure. Petty thefts are also common. Acts of violence may be a sequence of hallucinations and ideas of persecution. As regards the testamentary capacity of a paretic, the ordinary qualifications for capacity must be established, but it must be admitted that there may be periods of complete lucidity during which a proper will may be made. In criminal cases it may be set up by the prosecution that the crime, though perpetrated by a general paralytic, was still done during a period of sanity.

Heart-Block and Nodal Rhythm in the Acute Infections.—J. Cowan, G. B. Fleming, and A. M. Kennedy report a case of diphtheria, with full heart block, in which the auriculo-ventricular bundle and node were found to be involved in an acute inflammatory process, and similar lesions were present in the auriculo-ventricular bundle in a case of malignant endocarditis in which conductivity was defective. In three cases of acute endocarditis, with nodal rhythm, the auriculo-ventricular node was acutely inflamed, the bundle being only and but slightly affected in one instance.

Salvarsan in Syphilis.—A. Foerster states that salvarsan is of special value where rapidity of action or concentration of treatment is desirable—*e.g.*, for the removal of certain infective lesions, for patients whose conditions of life render a regular treatment impossible. It is widely applicable, as its toxicity is small. Cardiac disease, syphilis of the nervous system, and concomitant grave maladies are its chief contraindications. The intravenous method is the only recommendable one. Repeated medium doses are preferable to a few large ones. Its use is indicated where mercury has failed. In very early cases an attempt at aborting the disease by excising the chancre and administering salvarsan is advisable. In florid secondary syphilis combined salvarsan and mercury treatment should be instituted and persevered with. The severe tertiary cases should also be submitted to this combined treatment. In mild tertiary cases salvarsan recommends itself by the rapidity of the removal of the lesions and by the long duration of the subsequent latency. Truly malignant cases are as hopeless under salvarsan treatment as otherwise. In late latent cases and in parasyphilis the administration of salvarsan presents no utility.

Syphilitic Aortitis with Valvular Incompetency.—A. Morison notes that syphilitic aortitis with valvular incompetency, though a distinct clinical entity, is a type of valvular disease which is not always recognized as such, although, with reasonably careful investigation and reflection, it should not fail to be detected. The patient affected with specific aortic valvular disease is usually a man and generally comparatively young, but not a youth. His age varies from 30 or 35 to about 50. Even on careful investigation, and, as a rule, no history of rheumatic or scarlet fever is to be elicited. Nor is there a history of physical disability in earlier life. The patient has usually followed some active calling, and often that of a soldier or sailor. Ultimately he becomes dyspneic on exertion, frequently complains of attacks of pain in his chest or epigastrium, and on examination reveals aortic valvular disease with consecutive enlargement of

the organ. If he fails to respond to treatment (as he frequently does at the stage at which he presents himself) and dies, the necropsy reveals an atheromatous aorta and puckering of the valves, which, considering the comparative youth of the patient in most cases and an absence of the history of the usual acute infections which induce heart disease, leads, even when syphilitic infection is denied, to a diagnosis of the consequences of that condition.

X-Ray and Radium Measurements.—S. Russ performed a series of experiments with the view of determining the intensity of penetration of the *x*-rays and the gamma rays of radium. He found that, starting with equivalent intensities at the surface, there would, under the experimental conditions, be a more marked diminution in the intensity of the gamma rays than of the *x*-rays, despite the fact that the absorption of the rays by the tissues was nearly thirty times greater in the latter than in the former case.

Membranous Rhinitis.—D. Forbes and H. P. Newsholme conclude that membranous rhinitis can readily produce similar disease in others. The connection between membranous rhinitis and diphtheria in a school outbreak, which the authors report was so intimate as to make it almost certain that there was a causal relation between them. It is a point of practical importance that the comparatively frequent occurrence and great infectivity of membranous rhinitis should be recognized widely. Missed cases of the disease would readily account for a not inconsiderable proportion of school diphtheria. An autogenous vaccine seems to be of definite value in removing membrane, getting rid of nasal discharge, and hence greatly reducing the infectivity of membranous rhinitis. But the vaccine does not appear to be capable of completing the work of elimination after the membrane has gone, *i. e.* after the vascular and lymphatic channels by which antibodies can reach the bacilli have been removed.

School Closure in Measles.—A. B. Raffle emphasizes the value of school closure as a means of preventing the spread of measles.

Operation for Hemorrhoids.—C. A. Bucklin describes his method of operating on hemorrhoids as follows: The patient having been prepared for this operation by taking upon retiring on the previous night the necessary cathartic is anesthetized to the state of muscular relaxation. The greased blades of a bivalve vaginal speculum that can be forcibly distended with a screw mechanism are instantly introduced just through both sphincters sufficiently to insure that they are stretched when the blades are expanded. Five minutes are taken distending the blades to the proper size. The screw is now reversed one turn which causes the blades to relax from their strong contact with the mucous membrane of the anus sufficiently to allow the speculum to be slowly rotated and manipulated for the purpose of exposing the lining of this opening for inspection. Hard stumps resulting from previous hemorrhoids are removed with the forceps and a knife. Other forms of this disease are treated with the forceps and a No. 1 catgut ligature, after which the hemorrhoids are cut off outside of the ligatures; or when the swellings are too numerous they may be treated with hypodermic injections of 30 per cent. carbolic acid in alcohol. The slits made in the mucous membrane by operating are better closed by stitches of No. 1 catgut for the purpose of avoiding complications.

Investigations of the Motor Functions of the Alimentary Canal by Means of the *X*-Rays. A. F. Hertz.
The Importance of Pelvic Deposits in the Diagnosis of Abdominal Cancer. G. G. Turner.
Further Examples Illustrating Cases of Chronic Toxemias at Vittel. H. J. Johnston-Lavis.
An Address on Iodine as the Sole Dressing for Operation Wounds. R. Alcock.
A Lecture on a New Material (Duralumin) for Surgical Appliances. E. M. Little.
A Note on the Value of Anchored Dressings in Surgery. J. Lynn Thomas.
Erythema and Death Following Intestinal Catarrh. P. B. Unwin, and A. Eddowes.
A Preliminary Note on the Penetrating Power of Some Ointment Excipients. F. Gardiner.
Hydrocephalus as a Sequel to Shock. A. K. Armstrong.

Motor Functions of Alimentary Canal.—A. F. Hertz describes the advances made through the agency of the *x*-rays in the study of the motor functions of the alimentary canal in health and disease.

Pelvic Deposits in Diagnosis of Abdominal Cancer.—G. G. Turner emphasizes the fact that in cases of malignant disease in the upper abdomen, and especially of stomach cancer, while there may be no signs of dissemination to be made out on ordinary abdominal examination and no ascites, there may be quite a considerable deposit in the pelvis, easily recognizable on rectal examination and without any symptoms to point to its presence.

Chronic Toxemias.—H. J. Johnston-Lavis reports a series of six cases to show the good effects of the spa treatment at Vittel, France, for the various chronic toxemias.

Iodine as the Sole Dressing for Operation Wounds.—R. Alcock reports the successful results that he has obtained in thirty-one cases in which, following a surgical operation, the operation area was treated by means of the application of tincture of iodine at intervals for the first few days, the incision being left exposed to the air and covered only by the patient's night clothes.

Duralumin for Surgical Appliances.—E. M. Little states that this metal is an alloy of aluminum slightly heavier than that element. Its strength, however, is about the same as that of mild steel of the same bulk. Like brass, it can be made stiffer by hammering, and it is supplied in varying degrees of hardness, according to the purpose for which it is required. It is practically noncorrodible, being scarcely affected by prolonged exposure to a concentrated solution of sodium chloride, ammonium sulphate in 10 per cent. solution, ammonia, sulphuric or nitric acids, sulphuretted hydrogen solution, or sea water. Caustic alkalies, however, attack it quickly. Duralumin takes a high polish, which is scarcely dulled by prolonged exposure to the air, even to the air of London. It cannot be brazed, but it can be soldered; as soldering has an annealing effect on it, it is not often advisable to use solder. Nor can it be tempered like steel, but the hardening effect of hammering or rolling takes the place of tempering to some extent. The author has found duralumin well adapted for orthopedic appliances, because of its strength, lightness, and freedom from corrosion.

Anchored Dressings in Surgery.—J. L. Thomas, in operations on regions difficult to bandage, confines the wound with a simple anchored dressing, that is, some of the sutures of the wound are tied around the dressing to keep it in place.

Erythema and Death Following Intestinal Catarrh.—P. Brooke Unwin and A. Eddowes report the case of a child under two years of age in whom death followed an erythematous eruption secondary to intestinal catarrh.

Penetrating Power of Ointment Excipients.—F. Gardiner, as the result of his experiments, points out the superiority of olive oil and cedar oil among liquid excipients, the former being the better; goose grease is first among the more solid fats, and benzoinated lard comes next. Glycerite of starch with cold cream, glycerite of starch with lanolin, "ungt. ophthalmicum basicum" and cold cream are the best of the combinations, and are placed in order of merit.

Hydrocephalus Following Shock.—A. K. Armstrong

reports the case of a man, aged fifty-four years, who succumbed to hydrocephalus, apparently resulting from mental shock.

Münchener medizinische Wochenschrift.

January 23, 1912.

Treatment of Acidosis with Alkalies.—Marchand shows that although infusion of a patient having diabetic acidosis with solution of an alkali can at most prolong life for a brief interval and hardly marks an advance in therapeutics, there may be conditions of acidosis of nondiabetic nature in which such intervention not only saves life for the occasion but may also lead to permanent recovery. The type of such an acidosis would naturally be that which results from acute poisoning so-called with strong acids, and this is most often to be looked for in suicidal attempts where a large volume of acid is swallowed deliberately. In a case of sulphuric acid poisoning of this character, in addition to the local effects of the acid, there was a well marked syndrome of acidosis, consisting of coma following an initial motor restlessness and cyanosis (the latter aggravated by edema of the glottis). A solution of magnesia was first introduced into the stomach and trachetomy was performed. Then 300 c. cm. of 5 per cent. sodium carbonate solution was infused into the veins. The patient immediately came out of his coma, and later voided an alkaline urine and passed freely alkaline fluid feces. The complete recovery of the patient showed that the injury to the nerve centers was not permanent but due only to the deprivation of alkali as a result of absorbing the free acid. In such cases the passage of such strong alkali through the tissues would itself be injurious so that the intravenous is the proper method of exhibition from every viewpoint. A thrombus may form *in situ*, so that some danger exists of its extension toward the heart. For this reason the vena basilica should be chosen for infusion, and generally speaking, the greater the distance from the heart the less the likelihood of fatal thrombosis.

Treatment of Cutaneous Scars.—Thilo appears to have been at work for the past 25 years in developing a technique for offsetting all the disadvantages of cicatrices following injuries. These are many, comprising vulnerability, unpleasant sensations, deformity, interference with function, unsightliness, etc. There is nothing new or startling about the technique which consists in a thorough persistent application of all useful measures, such as massage, hydrotherapy, mechanical devices, etc. The cosmetic and functional results attained are sometimes surprising. In a very extensive scar of the lower extremity resulting from a burn, the scar area was covered with adhesive plaster strips as a protective, and through the latter, massage and passive motion were carried out, beginning about two months after the injury. The leg was further kept under a weight extension for part of the time. After the leg had been gradually straightened by thus antagonizing the scar contraction it was placed in a splint. After this start, the natural efforts of the patient seemed sufficient to correct further deformity and 20 years later the scar is seen to be perfectly smooth and supple. The early massage has to be done under the plaster, but at a later period the author applies frictions with sand and oil or water. The subsidence of itching and tension shows the therapeutic efficacy of this procedure. The influence of this massage on the circulation has also been utilized by the author in such opposite conditions as erysipelas of the leg and cold feet. In the former, which was treated on the same principle as an extensive recent scar, the pain and swelling were almost gone within four days.

Serum Death and Anaphylaxis.—Dreyfuss reports a case which shows the danger of giving second injections of the same curative serum within a two years' interval. Following an injection of diphtheria antitoxin, a boy who had already been recipient of a prophylactic injection at that period died within half an hour. Investigation showed that it was the only accident traceable to a series of 3,000 vials of one of the leading manufacturers. The symptoms, —itching, convulsions and vomiting—represented a toxic syndrome, due evidently to supersensitiveness following the original injection. The lesson is clear that if first injections are made with horse serum specimens, second injections should be practiced with a special serum obtained from some animal other than the horse.

Deutsche medizinische Wochenschrift.

February 1, 1912.

Bloodless Dilatation of the Nasal Fossæ.—Killian states that in 1910 he recommended, for the first time, that the inferior turbinal be fractured in connection with mucosa resection. He has since come to the conclusion that fracture alone has a distinct field of usefulness, not that it gives better results, but that more people would submit to the bloodless method, both on general principles and because it greatly abridges the period of treatment. Naturally, only the lesser degrees of deformity are suited to this conservative plan. After the application of adrenalin-cocaine the turbinal is forced outward with the Luc-Brüning forceps until it is heard to crack. The author has also devised a special instrument for the purpose. A deviated septum may sometimes be fractured at the same sitting.

Ischemic Paralysis of a Limb from Arterial Occlusion.—Aoyagi of Tokio gives a monographic account of this condition, which is of very rare incidence when compared with the form caused by construction. He reports a personal case in much detail and cites similar cases from literature. In 1899 Lapinsky reported a series of six cases. In the prevailing type the plugging of the arteries appears to occur as part of a general infection—pneumonia, typhoid fever—or as the result of an endocardial lesion. A histological study shows that the terminal filaments of the sensory and motor nerves suffer more than any other structures from the ischemia, the muscles participating in a much lower degree. The converse is true in ischemic paralysis from constriction.

A New Protozoan Disease.—Under the name granuloma telangiectodes europeum Schridde describes an affection which he believes to be by no means a rarity in Germany. It is manifested chiefly by ulcers upon the fingers and hands, but lesions may occur elsewhere on the limbs or in fact almost anywhere on the surface. The most striking feature is the mushroom-like proliferation, which at once suggests verruga peruana or granuloma telangiectodes tropicum. It may be the botryomycosis described by French authors. While it does not attack the bones of the fingers primarily, it may do this by direct extension, and this destructiveness, with the fungating appearance, would cause the lesions to be reckoned clinically as sarcomata. The present study is almost wholly histological, and the demonstration of a protozoan cause is not yet complete.

Progress in Preventing and Treating Seasickness.—According to Peters, physician on the Hamburg-American line, the hygienic exhibitions in Germany will contain many new devices of a physical and mechanical nature for preventing and offsetting the effects of wave motion on the passengers of steamships. Something in this direction was introduced in 1905 by the author—a vibrating chair, designed to affect favorably the circulation, which was supposedly interfered with by the ship's motion. The effects could be studied through changes in the circulation of the external ear. Under the influence of the seasickness the latter became pale, but vibration restored the vasomotor equilibrium. The apparatus was a failure, however, in practice; and active locomotion gives better results.

Insurance Medicine.

BLOOD-PRESSURE ESTIMATION IN INSURANCE WORK.

For some years now it has become a recognized thing that the blood-pressure is a useful and important guide to the state of health, and in some cases where a man may look healthy the blood-pressure may give valuable information, as by it we find that the arteries are not what they appear to be and that cerebral hemorrhage may occur in spite of the outside appearance of perfect health.

Various instruments exist for the measurement of the blood-pressure—in fact we may say that there are at least fifty different models of blood-pressure instruments—sphygmomanometers. Most of these are graduated to indicate a normal blood-pressure equal to from 120 to 140 millimeters of mercury and so comparisons of the readings of the different instruments are readily made. Readers of foreign literature, however, should remember that in some countries in Europe, but especially in France, the instrument most commonly in use is the instrument of Potain, and this is not graduated as the others. Potain, in his work on blood-pressure, gauged the normal as 150 to 100 for man and 140 to 180 for woman. (Potain: "La pression artérielle de l'homme à l'état normal et pathologique," 1912.) Now here we have an instrument consisting of a small rubber bulb attached to the ordinary registering apparatus by a rubber tube and this Potain instrument gives the normal as 150 to 100. The 150, of course, corresponds to normal blood-pressure, but it does not correspond to 150 mm. of mercury, and this is the point against which we must be on our guard. If thus an examiner states that with Potain's instrument the blood-pressure is 100 mm., we are still within limits, whereas with the Riva-Rocci instrument the registering of 100 mm. would be high.

This information may be of use to the medical officers of companies with European business, as a misunderstanding may easily occur in consequence of the considerable difference which exists between the reading of Potain's instrument and the reading of other instruments.

Injuries of the Liver.—Knepper says that the most difficult of medical problems in accident insurance consists in determining the part played by accidental injury in the causation of disease of internal organs. He has had the good fortune to observe many cases of accidental injury of the liver and spleen and to follow them to the development of internal disease, and has gathered the material in a systematic fashion.

The liver is of extreme importance in questions of accidental internal injury. Its surface is very large, some portions of it are very insufficiently protected, and it is, therefore, easily injured. Moreover, dislocation of the organ, inflammation, or abscess formation frequently follow. Injuries of the liver may be open; that is, accompanied by a wound of the abdominal walls, or closed. Open wounds are easily diagnosed if the direction of the injuring force is recognized, the wound being probed if necessary. It must be remembered that a penetrating injury, if deep enough, must strike the liver because this organ has no such faculty of slipping out of the way as some other intraabdominal organs. Penetrating wounds are always accompanied by injuries of the peritoneum, and are, therefore, always very serious. Such injuries frequently occur in working with agricultural instruments, machinery, etc., and infection is, therefore, almost always a consequence. Death in such cases must, of course, be referred to the accident; if recovery follows and, later, symptoms of pain, tenderness, inability to do hard work, gastrointestinal disorders, etc., are complained of, they may well be due to the adhesions and scars following the injury, and must be so interpreted by the insurance physician.

Subcutaneous injuries of the liver are usually due to directly acting violence of blunt character, such as kicks, blows, etc. External evidences of the injury may be absent or much less severe than the internal injury, and the degree of violence necessary to produce injuries of the liver may be surprisingly slight. Especially fragile is the liver substance in consequence of infectious disease, various degenerative changes, syphilis, tuberculosis, neoplasm, etc. The degree of injury varies a great deal from slight lacerations accompanied by hemorrhage and ending in scar formation and recovery to extensive trauma involving a great deal of the liver substance and ending in death. Knepper details three cases of death after such injuries, with autopsy findings. One other patient, who sustained a fatal tear of the liver, together with other injuries, was able to mount a wagon right after the accident and hold a conversation with the bystanders!

The following symptoms should be looked for in the diagnosis of liver injuries: (1) Pain in liver region, with tenderness upon pressure. This is seldom absent, except in cases of "euphoria" of shock, but may be marked in simple hyperemia with capillary hemorrhages. (2) The so-called "consensual" pain in the right shoulder, which is sometimes so marked as to limit the use of the right arm, the muscles of which may show atrophy. (3) Signs of internal hemorrhage combined with those of shock; that is, a small, hardly perceptible pulse, paleness of the face and of the mucous membranes, frequent yawning, nausea and vomiting, and a rigid abdomen, with dullness below or in the flanks. (4) Frequently there are marked anxiety and fear of death, which are very characteristic for severe injury of the abdominal organs, and especially of the liver. (5) Icterus is present in about 20 per cent. of the cases and may appear early, in the course of the first two weeks, because of resorption of escaped bile, or late because of mechanical obstruction of the bile passages. If present, jaundice is of much diagnostic importance; its absence does not exclude injury of the liver. (6) Increase of liver dullness, which may be very little marked in plain hyperemia of the organ or very extensive in subcapsular hemorrhage. (7) Hardening of the liver, which is usually a late consequence of chronic inflammation engendered by the injury.—*Zeitschrift für Versicherungsmedizin*, November, 1911.

The Consequences of Liver Injuries.—Knepper continues his exhaustive study of liver injuries. He says that microorganisms easily gain access to an injured organ and cause inflammatory reaction. The inflammation may subside or it may result in a circumscribed abscess, which may be latent for months or even years, and finally give characteristic evidence of its presence. On the other hand, it may perforate into the neighboring organs, the pleural cavities or the stomach, for instance, or cause a general infection of the peritoneal cavity. Rarely it may adhere to the external abdominal wall and perforate externally.

Occasionally a local or even a general peritonitis arises after an injury of the liver, without a preliminary abscess formation. Such peritonitis may be recovered from and result in adhesions, or may end fatally. Perihepatitis may first give rise to symptoms when the patient tries to take up his work after recovering from an injury of the liver. Frequently an examining physician may be unable to convince himself of the actuality of the patient's complaint, and thus may cause much injustice to him in case of a claim for indemnity. Knepper details three examples

of liver injuries, one followed by the formation of an abscess, another by perforation into the stomach, and the third resulting in a troublesome perihepatitis.

Knepper then considers injuries of the gall-bladder and bile passages. The gall-bladder may be torn at the time of liver injury and free bile in the peritoneal cavity may necessitate an operation. Normal bile, however, may cause no irritation of the peritoneum and no infection. On the other hand, rupture of a gall-bladder containing stones or the seat of an ulcer usually results in infection of the peritoneum. Trauma is supposed to have some etiological relation to the appearance of gallstones, but it is more probable that it simply makes latent gallstones manifest. Occasionally trauma may result in a cholecystitis in a gall-bladder containing stones.

The following more remote consequences of liver injuries must be likewise considered: wandering liver, hepatic cirrhosis, diabetes mellitus, and carcinoma of the liver. Opinions are divided in reference to the rôle played by trauma in the etiology of wandering or floating liver. Such a consequence is certainly very rare. Occasionally an acutely inflamed and enlarged liver may be mistaken for a wandering liver, but the condition is transient and later examinations usually show the actual state of affairs. Knepper says that Szaweljew has gathered 117 cases of wandering liver, in sixteen of which trauma seems to have been the etiological factor.

Occasionally trauma is held to be of etiological importance in liver cirrhosis. Senator has admitted this possibility in giving an expert opinion in a suit for damages. He says that only rarely a cirrhosis may have arisen from damage of liver tissue and consequent overgrowth of connective tissue: it is more reasonable to suppose that a perihepatitis takes place and the inflammatory condition slowly overtakes the liver itself. However, it is much more probable that an already existing cirrhosis is made evident by the injury than that the injury causes a cirrhosis. That trauma may increase the symptoms of cirrhosis must be granted.

The question whether diabetes mellitus may or may not develop after a liver injury is a different one, and the opinions of authorities are divided. Ebstein thinks diabetes may follow any general injury of the organism, such as may occur with concussion. Claude Bernard, Zimmer, and others claim to have seen such cases of hepatic diabetes. Kausch, in a study of the etiology of diabetes, tells of 150 consecutive cases of diabetes, in none of which was trauma mentioned as a possible factor. Senator names 1 per cent. of this etiology among his 800 cases. On the other hand, diabetes may have existed before the injury without having been recognized. A transient glycosuria, too, occurring after injury may at first be mistaken for diabetes. Of course, an injury of the pancreas may occur at the same time as the liver is injured, and this may be responsible for the development of diabetes after such an injury. An existing diabetes is frequently made worse by any trauma.

The rôle of trauma in the etiology of liver carcinoma is also very doubtful. We know so little of the etiology of cancer in general that caution is necessary in judging malignant disease in any aspect. Frequently, too, an apparently primary cancer of the liver, symptoms of which may be complained of by the patient, is proved to be secondary to a neoplasm elsewhere in the stomach, or breast, for instance. The primary cancer may be very small, while the secondary growth in the liver is of enormous size. On the other hand, cancer of the gall-bladder seems to have something to do with the chronic injury produced by gallstones, and in such cases a single intense trauma may also have some etiological bearing upon the disease. A preexisting cancer can, of course, be made much worse by trauma: it may either be made to grow and form metastases quickly by such an occurrence, or may break down rapidly and give rise to very acute symptoms. Cancer anywhere, however, is subject to such variations in its program that the rôle of trauma must be very carefuly weighed in each case; frequently the change in the disease may be shown to have preceded the injury.—*Zeitschrift für Versicherungsmedizin*, November and December, 1911.

Traumatism and Heart Disease.—J. C. Wilson reports the case of a man who received a severe contusion on the chest followed by hemoptysis in recurring attacks. The patient's general health had been good and there was no evidence of rib fracture. The immediate effects of the accident were quickly recovered from and there were no very marked symptoms of pulmonary disease. The patient had never had rheumatism, but developed the signs and symptoms of a well-developed mitral stenosis with good compensation, but with a marked tendency to bronchopulmonary hemorrhage. The author remarks that this symptom in mitral stenosis is much more frequent than the descriptions in the literature of that disease would indicate. He quotes some authors who have noticed cases of heart disease following traumatism, and he thinks that the leucocytosis of 16,600 at the late period after the accident and some evidence of a persistent, though gradual, subsiding congestion of the lower lobe of the left lung, probably associated with a low-grade chronic bronchopneumonia, may be invoked to account for the continuing blood loss in connection with an advancing mitral stenosis. The hemorrhagic cases of this disease are often incorrectly regarded as obscure cases of pulmonary tuberculosis. Allbutt's "System of Medicine" is quoted as follows: "Traumatic influences occasionally give rise to the lesions of mitral obstruction. Indirect injury very rarely produces any changes in the mechanism of the mitral valve unless there has been previous disease, but direct violence, such as a blow on the anterior chest wall, is not a very rare cause of the affection." Bernstein, in 1896, collected the reports of cases of heart disease directly following traumatism, 124 in number, but a careful examination of this list shows a very limited number in which the valves were implicated and not one which presents the characters of the author's case. Stern's monograph, "Die traumatische Entstehung innerer Krankheiten," contains a limited number of further cases of valvular disease. Riesman reported a case of mitral stenosis of traumatic origin in which the injury was indirect, being the result of violent exertion on the part of the patient in fleeing from footpads. In most of the cases reported the signs of valvular lesions have been attended by indications of acute endocarditis and in a large proportion of these cases the diagnosis has been either established or confirmed by necropsy.—*Journal of the American Medical Association*, February 10, 1912.

Arteriosclerosis in Relation to an Accident.—Pickenbach tells of a riding master, 64 years old, who was found in collapse and unconscious in the riding school. He recovered consciousness after stimulating medication, and it was then discovered that he was suffering in addition from a large hematoma and contusion of the right hip and right side of the abdomen. The patient insisted that he was kicked by a horse while alone in the riding school, and sustained the injuries because of the kick and the fall to the ground. However, he showed advanced arteriosclerosis and gave the history of attacks of dizziness. Pickenbach considers that in all probability the man fell off a horse while in such an attack and consequently was not entitled, according to the conditions of insurance, to accident indemnity. Because of the impossibility, however, of proving either explanation of the injuries, a compromise was effected.—*Aerztliche Sachverständigen-Zeitung*.

Book Reviews.

CLINICAL DIAGNOSIS. A Text-Book of Clinical Microscopy and Clinical Chemistry for Medical Students, Laboratory Workers, and Practitioners of Medicine. By CHARLES PHILLIPS EMERSON, A.B., M.D., late Resident Physician, the Johns Hopkins Hospital, and Associate in Medicine, the Johns Hopkins University; Professor of Medicine, Indiana University School of Medicine. Third Edition. Price $5.00. Philadelphia and London: J. B. Lippincott Company.

EVEN in the comparatively short time of the five years that have elapsed since the book first appeared the development of the subject with which it deals may well be termed tremendous. The laboratory aspects of diagnosis are increasing in significance to such an extent and are enlisting the efforts of so many workers that new methods are being suggested with almost bewildering rapidity. Many of these are of little value, some have only temporary interest, and a few will no doubt be found permanently useful. Properly to sift this enormous amount of material is a task whose magnitude can be fully appreciated only by those who are themselves engaged in it, and a careful survey of this new edition of Dr. Emerson's book reveals most admirable discrimination in the selection of the additions. It goes without saying that the volume has been greatly enlarged and it is a pleasure to find with what thoroughness the literature has been reviewed. Omissions of any moment seem to be few and subjects of recent interest such as the Wassermann reaction and the use of the viscosimeter are fully discussed. Benedict's very easy and reliable method for determining the total sulphur in the urine is not mentioned, however, nor is the meiostagmin reaction, while the large amount of recent work that has been done on the glycyltryptophan test might also be thought to deserve discussion. A feature that makes the book of especial value is the prominence that is given to the interpretation of the results of the various diagnostic procedures and the introduction of much matter which is the result of the author's own observation. The chapter on the sputum is a good example of this and forms by far the best presentation of the subject with which the reviewer is acquainted. The new edition has been so thoroughly revised and so extensively enlarged as to make it to all intents a new book which possessors of the former editions will be eager to have and which may be most warmly commended to those who are as yet not familiar with it.

THE WELLCOME PHOTOGRAPHIC EXPOSURE RECORD AND DIARY. U. S. A. Edition. Price $1.00. London and New York: Burroughs, Wellcome & Co., 1912.

THE new edition of this exceedingly useful pocketbook has undergone no change in its general arrangement, but comprises a number of valuable additional tables and formulæ. It is without doubt the most satisfactory of all similar publications, and photographers who have once become accustomed to its use would not willingly dispense with it.

AN ARMY OFFICER ON LEAVE IN JAPAN, Including a Sketch of Manila and Environment, Philippine Insurrection of 1896-7, Dewey's Battle of Manila Bay, and a Description of Formosa. By L. MERVIN MAUS, Colonel United States Army. Illustrated. Price $1.50. Chicago: A. C. McClurg & Co., 1911.

IN this most entertaining book Colonel Maus does not appear himself as the writer, but has introduced the narrator in the person of a fictitious Mr. Rhodes, an employee of the National Bureau of Commerce, who is sent on a special mission to the East and makes the journey in company with an army officer, known as the Major, and a member of the Philippine judiciary, known as the Judge. These gentlemen are familiar with the conditions, past and present, of the countries visited and possess a vast fund of useful information and anecdotes which they impart to their companion and which is faithfully recorded by him. In addition to a delightful description of the principal places in Japan as far north as Nikko, the book contains chapters on Manila, the Philippine insurrection of 1896-7, Dewey's battle, Formosa, the religions of Japan, the persecution of the Catholics in the seventeenth century, an historical sketch of Japan, including the war with China, the Boxer trouble in 1900, the Russo-Japanese war of 1904-5, and most useful guide-book information on railroads, rickshas, guides, hotels, etc., in Japan for the use of the traveler. The author is a most entertaining raconteur and one may pass a few delightful hours in reading the book, even if he never has seen nor expects to see Japan. For one going to Japan the book will prove invaluable, not only for pleasant reading on shipboard but as a trustworthy guide-book for the places to be visited. The Appendix contains also several tables of the estimated cost of a trip to this fairy land not yet quite spoiled by Western civilization.

NACHWEIS UND BESTIMMUNG VON GIFTEN auf BIOLOGISCHEM WEGE. Eine Anleitung fur Pharmakologen, Gerichtsärzte, Gerichtschemiker, und Apotheker. Von Dr. phil. et med. Hermann Fühner, Privatdozenten fur Pharmakologie an der Universitat Freiburg i. B. Berlin und Wien: Urban und Schwarzenberg. Price $2.25 and postage. New York: Rebman Company, 1911.

TEXTBOOKS on chemistry, toxicology, or forensic medicine frequently include a few methods for the testing of poisons biologically, but in this volume the author has brought together for the first time in one book methods for thus recognizing some fifty poisonous substances. He describes the specific effect of these poisons on algæ, yeasts, and moulds, as well as upon frogs, mice, rabbits, and cats. Methods and results are exactly pictured and no reference is made to the physiology of the subject, so that no confusion will be present on that account. For this reason any person reasonably familiar with laboratory technique should be able easily to follow any of the tests. Quantitative as well as qualitative methods are described and in many instances far exceed in delicacy the best chemical methods at our disposal. Their value is greatly enhanced by the fact that the author has himself perfected each test. The book should be of great value to the medicolegal expert and to the pharmacologist and portions of it will no doubt in time find their way into the Pharmacopœia.

FURTHER RESEARCHES INTO INDUCED CELL-REPRODUCTION AND CANCER. Consisting of papers by H. C. Ross, M.R.C.S. England, L.R.C.P. London; J. W. CROPPER, M.B., M.Sc. Liverpool, and E. H. Ross, M.R.C.S. England, L.R.C.P. London. With Illustrations The McFadden Researches Price $1.00. Philadelphia: P. Blakiston's Son & Co., 1911.

THIS small volume consists of a paper on chemical substances which cause cell division of human lymphocytes; descriptions of methods of making permanent fixed films showing such divisions and of inducing division of cells floating in proper solutions; a paper on the action of "auxetics" upon erythrocytes; and some remarks upon cancer in pitch workers. Accompanying the volume is a circular letter, a copy of one from Dr. Ronald Ross to the publishers, giving details of the controversy between H. C. Ross and a committee of eminent men who acted as his "patrons," but later disclaimed all responsibility for his book on Induced Cell-Reproduction and Cancer. This letter apparently shows that Dr. H. C. Ross has been more sinned against than sinning. The chief concern of the reader interested in the subject, however, consists in having to pay one dollar for a few papers which should have reached him as free reprints had they been published in medical journals and not as an independent book, because of the controversy.

The papers themselves, beyond descriptions of methods, add nothing to the statements in Dr. Ross's book, mentioned above. They should prove of interest to those who have read that book. Without it they are almost unintelligible.

DIE STÖRUNGEN DES VERDAUUNGSAPPARATES ALS URSACHE UND FOLGE ANDERER ERKRANKUNGEN. Von Dr. HANS HERZ in Breslau. Zweite, umgearbeitete und vermehrte Auflage. 1 Teil: Die Krankheiten des Blutes, des Stoffwechsels, der Konstitution in ihrer Beziehungen zum Verdauungsapparat. Price 6 marks. Berlin: Verlag von S. Karger, 1912.

THE first edition of this book was published thirteen years ago. The advance of our knowledge on the relation between gastrointestinal disorders and other affections has been so marked in the meantime that this edition is almost a new work. The first volume, now before us, considers anemia, leucemia, pseudoleucemia, hemorrhagic diseases, gout, diabetes, obesity, affections of the thyroid activity and disturbances of metabolism that are dependent uopn gastrointestinal disorders. Each chapter is more of a résumé of the published facts and theories of other authors than merely an expression of the author's views. This makes the book of value for reference. In general Herz's study shows no very striking or original observations, yet should prove of value to the internists as well as to specialists in the narrower field of gastroenterology. Its perusal may serve to keep the physician from the error of narrowness, which often follows in the train of modern specializing in one field of work.

THE CONQUEST OF THE NERVES. By J. W. COURNEY, M.D. Price $1.25. New York: The Macmillan Company, 1911.

THIS is a booklet of ten chapters, containing an intelligent interpretation of the success of Christian science, "Emmanuel movement," New Thought, etc., in the treatment of certain affections of the nervous system. The author shows that the physician is frequently responsible for the despair of a nervous patient which makes him turn to some ostensibly new and mystic curative creed. He then analyzes the more simple affections of the nerves and shows how a sufferer from "nerves" may find a cure in himself and in orthodox medicine, rather than in Christian science, for instance, which compels him to do violence to his intelligence or, in plain English, "to make a downright fool of himself."

The book is very well written, in a clear and entertaining style, and can be safely recommended by physicians to their patients. The doctor, too, may find in it valuable hints for the treatment or rather the management of persons suffering from functional nervous disease.

ABHANDLUNGEN AUS DEM GEBIETE DER GEBURTSHILFE UND GYNAEKOLOGIE. Mitteilungen aus der zweiten Frauenklinik der Königl. ung. Universität zu Budapest. By Prof. Dr. W. TAUFFER, Direktor der Klinik, Vol. II, No. 1. Price 4 marks. Berlin: S. Karger, 1912.

THE work here referred to includes contributions from the Gynecological Clinic at Budapest, presided over by Professor Tauffer. The contents comprise the following six articles by various members of the same. A clinical study of placenta previa and its treatment, by Frigyesi, based on a study of 110 cases which occurred in the clinic; pyelitis in pregnancy and its treatment, based on an investigation of 26 cases, which leads to the claim that a waiting policy in such cases is not to be recommended before labor and if the condition occurs during the puerperium without any improvement in the clinical signs taking place within forty-eight hours catheterization of the renal pelvis is to be resorted to; the preparation of the abdomen for gynecological operations, by Scipiades, a paper in which the writer advises the preparation of the skin with applications of acetone-alcohol and tincture of iodine; the application of Momburg's constriction belt in obstetrics, also by Frigyesi: inversio uteri associated with hypoplasia of the adrenal system, by Mansfield; a study of a case of spontaneous inversion of the uterus in a primipara, in which it was found that a high degree of hypoplasia of the adrenals was present, together with a diminution of the adrenalin content to about one-quarter of the normal amount, which leads to the building up of an hypothesis that such extreme conditions of atony without any local anatomical basis are due to the lack of this tonic hormone; and, finally, pregnancy and fibroids, by Scipiades, in which the relation between these tumors and sterility is discussed. The above treatises constitute a very valuable addition to gynecological literature.

HANDBUCH DER INNEREN MEDIZIN. Bearbeitet von L. BACH, Marburg; J. BAER, Strassburg; G. VON BERGMANN, Berlin; R. BING, Basel; H. CURSCHMANN, Mainz; W. FALTA, Wien; W. A. FREUND, Berlin; H. GUTZMANN, Berlin; C. HEGLER, Hamburg; K. HEILBRONNER, Utrecht; R. HEINZ, Erlangen; G. JOCHMANN, Berlin; K. KISSLING, Hamburg; O. KOHNSTAMM, Königstein, W. KATZENBERG, Hamburg; P. KRAUSE, Bonn; B. KRÖNIG, Freiburg; F. KÜLBS, Berlin; F. LOMMEL, Jena; E. MEYER, Berlin; E. MEYER, KÖNIGSBERG; L. MOHR, Halle; P. MORAWITZ, Freiburg; E. MÜLLER, Marburg; F. ROLLY, Leipzig; O. ROSTOSKI, Dresden; M. ROTHMANN, Berlin; C. SCHILLING, Berlin; H. SCHOTTMÜLLER, Hamburg; R. STAEHELIN, Basel; E. STEINITZ, Dresden; J. STRASSBURGER, Bonn; F. SUTER, Basel; F. UMBER, Altona; R. VON DEN VELDEN, Dusseldorf; O. VERAGUTH, Zurich; H. VOGT, Strassburg; F. VOLLHARD, Mannheim; R. WITTMAACK, Jena; Herausgegeben von Professor Dr. L. MOHR, Direktor der medizin. Poliklinik zu Halle (Saale) und Professor Dr. R. STAEHELIN, Direktor der medizin. Klinik zu Basel. Erster Band: Infektionskrankheiten. Mit 288 zum Teil farbigen Textabbildungen und 3 Tafeln in Farbewdruck. Price 26 Marks. Berlin: Verlag von Julius Springer, 1911.

THE imposing array of names that greet the reader as he scans the title page of the first volume of this new "Handbook of Internal Medicine" gives him an inkling of what he is to expect on the succeeding pages. The term handbook is modest indeed, for it characterizes a six-volume work, the first volume of which contains over 1,000 pages. With characteristic German thoroughness this work aims to present the modern aspects of internal medicine, chiefly from the viewpoint of pathological physiology, so far as this is rendered possible by the present stage of research. Pathological anatomy is not accorded that overwhelming share of attention which it attracted in the early days of medicine; but the claims of the clinical laboratory in conjunction with those of the bedside are given greater emphasis. At the same time the practical needs of the everyday practitioner are amply supplied. The first volume takes up the infectious diseases. It is difficult to single out any one feature which deserves commendation, so admirably have all the topics included in this volume been presented. The opening chapters from the pen of O. Rostoski deal with infection, immunity, anaphylaxis, and the diagnostic and therapeutic value of the immunity reactions. The acute exanthemata are described by P. Rolly, while F. Krause discusses pertussis, influenza, herpetic fever, epidemic parotitis, diphtheria, tetanus, typhus, and Asiatic cholera. G. Jochmann is the author of the article on dysentery. The typhoid diseases are discussed in an extensive chapter of 200 pages by H. Schottmuller. An important chapter is that on the septic diseases by G. Jochmann, who also treats of erysipelas, acute articular rheumatism, and cerebrospinal meningitis. Poliomyelitis is dealt with extensively by E. Müller. The other subjects included in this volume are acute miliary tuberculosis, leprosy, plague, Malta fever, protozoal diseases, yellow fever, dengue, beriberi, and the zoonoses: actinomycosis, glanders, foot and mouth disease, trichinosis, anthrax, and rabies. The volume is profusely illustrated and well printed on excellent paper.

A STUDY IN TROOP LEADING AND MANAGEMENT OF THE SANITARY SERVICE IN WAR. By Major JOHN F. MORRISON, General Staff, United States Army, and Major EDWARD L. MUNSON, Medical Corps, United States Army. Approved by the Surgeon General United States Army. Published by authority of the War Department. Price $1.50. Agents, United States Cavalry Association, Fort Leavenworth, Kans., 1910.

THIS book contains a graphic description of the operations of a division of troops in battle and describes in minute detail the management of the sanitary service. As an exposition of the field duties of the medical department in battle this book has not been equaled by anything heretofore published. The book is of great interest to any one who wishes to obtain an idea of what the sanitary service has to do before, during, and after an engagement. It emphasizes the great importance of military and tactical knowledge on the part of medical officers, and shows that the function of the sanitary service in the removal of wounded from the field is of the utmost importance, and that the removal can only be accomplished efficiently by officers who are familiar with the art of war and with military methods and means of administration. The book is as easy to read and as interesting as a good novel.

THE PRINCIPLES OF SANITARY TACTICS. A Handbook on the Use of Medical Department Detachments and Organizations in Campaign. By EDWARD LYMAN MUNSON, A.M., M.D., Major, Medical Corps, United States Army; Assistant Commandant, Field Service School for Medical Officers; Senior Instructor, Department care of troops, School of the Line and Staff College, Fort Leavenworth, Kansas. Approved by the Surgeon General, U. S. Army. Published with consent of the War Department. Price $2.00. Agents, U. S. Cavalry Association, Fort Leavenworth, Kansas. 1911.

THIS book is a handbook which is of the utmost value not only to medical officers of the military service, but also to all other staff and line officers. It has a large amount of information which should appeal to the general medical profession. It must be borne in mind that in any war which the United States undertakes against a first-class power there will be a demand made upon the medical profession of the country to supply between 20,000 and 30,000 medical officers. There were some 14,000 doctors employed upon the Federal side alone during the four years of the Civil War. These men came into the military service without previous training, and in the vast majority of instances absolutely ignorant of military matters.

Major Munson's book gives a very clear and distinct idea of the service that will be demanded of medical officers in our next war, and for that reason the book should appeal to those persons who are interested in the subject of national defence.

The introductory section of four chapters gives an admirable description of the history of the organization of the sanitary service and of its present arrangement.

The problems in the body of the book are complete as to detail and extremely well conceived and arranged.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 25, 1912.

DR. FRANKLIN A. DORMAN IN THE CHAIR.

Two Cases of Secondary Abdominal Pregnancy.—Dr. ROBERT L. FRANK reported these cases. He stated that primary abdominal pregnancy occurred so rarely that, until recently, its actual occurrence had not been satisfactorily proven. In order to demonstrate a primary peritoneal insertion of the ovum it must be shown that neither the ovary nor the tube had been involved. The two cases reported were primarily tubal, and secondarily underwent further development within the peritoneal cavity. The first case was one of ectopic gestation, probably arising from the fimbria ovarica, with beginning lithopedic formation. The patient, 31 years of age, was referred to Dr. Frank with the diagnosis of ectopic pregnancy, probably abdominal, with dead fetus. The history of the case showed that eight months before she presented herself she had had severe abdominal cramps in the right iliac region, lasting two and one-half hours. Two days later she fainted and later she suffered three more attacks of pain, 10, 13, and 18 days, respectively, after the first seizure. She did not menstruate for four months and considered herself pregnant. For the past four months menstruation had been regular, but scant. Examination revealed a uterus reaching almost to the umbilicus, and behind it a hard, slightly irregular mass which could hardly be palpated from above. Bimanual examination showed that the uterus was enlarged, anteverted, and elevated by a hard, semi-cartilaginous mass which occupied Douglas' cul-de-sac and reached laterally almost to the anterior superior spines. At operation a somewhat enlarged uterus, with a few small fibroid nodules on its posterior surface, was found. Behind the uterus and extending into the lowest portion of the Douglas' pouch was a hard, irregular mass the size of an orange, attached to the uterus, sigmoid, and pelvic parietes by fine velamentous adhesions. The right fimbrica ovarica was unusually long and broad, forming a band 2 cm. wide, which was lost in the mass. The tumor was freed without difficulty and the patient made an uneventful recovery. The specimen consisted of a black discoid mass, upon which was stretched a mummified fetus, still within its membranes. Microscopical examination showed that the black portion consisted of placenta. The *x*-ray demonstrated a complete fetal skeleton corresponding to the fourth month of gestation. The history showed that in the first month of gestation some disturbance took place, probably the gradual extrusion of an ampullary ovum, which continued to derive its blood supply from the fimbrina ovarica. At the fourth month the fetus died and mummification was well under way when interrupted by the operation. The second case was one of tubo-abdominal pregnancy with the insertion of the placenta on the posterior surface of the broad ligament and pelvic floor. This patient was a woman 35 years of age, who was sent to Mount Sinai Hospital for ruptured tubal pregnancy, and on admission was in a severe state of collapse, pulse 148, temperature 101.6°, respiration 32. The abdomen was distended, there was a bulging semi-fluid mass in the posterior fornix, and the various signs of pregnancy were noted. Operation was performed at once. The abdomen contained a large quantity of free blood and a live four-months-old fetus lay free among the coils of intestine. The uterus corresponded to a three months pregnancy. The outer third of the right tube was lacking and a large placenta was located attached to the posterior surface of the right broad ligament, the peritoneum covering the division of the aorta and slightly downward on the peritoneum of Douglas' cul-de-sac. On attempt to free the placenta the right broad ligament tore completely away from its attachments and the torn ovarian vessels retracted upward. They had to be ligated without previous exposure of the ureter owing to the desperate condition of the patient. Right salpingo-oophorectomy was performed and violent oozing continued from the bed of the placenta, making tamponing necessary. The posterior fornix was perforated from above and a gauze drain covering the bleeding area led out into the vagina. The patient did well for a few days when she began vomiting bilious fluid and complete obstruction supervened. The abdomen was reopened and the upper jejunum was found much distended. A kink was located high in the renal region produced by a large adherent blood clot which had angulated the intestine. The angulation was relieved and a tube enterostomy established, but the patient failed to rally and died five hours later. The specimen was a normal fetus 25 cm. in length with a cord 12½ cm. in length. The placenta was thin, circular, and 10 cm. in diameter. The outer one-third of the tube was lacking and in the torn end villi were demonstrated. Some important points necessary to an exact anatomical diagnosis were lacking; it was possible, however, to demonstrate that the placenta was directly attached to the parietal peritoneum in the location already described.

Multiple Fibroid Complicating Pregnancy; Hysterectomy; Recovery.—Dr. S. M. BRICKNER reported this case, which was seen by him in consultation on September 8, 1911, and admitted to Mount Sinai Hospital on September 9. Her last menstruation had occurred fifteen weeks before and her present illness dated back four weeks. She said that one day two months before her admission to the hospital she had had short sharp pain in the left side of the abdomen. Four weeks before she had an attack of sharp abdominal cramps and nausea, but no fainting, no collapse, and no spotting. The cramps lasted three days and then she noticed spotting for the first time. Four days later she had another attack of cramps; since that time she had continued to have these attacks, but had never vomited until the day before admission. Physical examination showed the abdomen to be irregularly and asymmetrically enlarged. To the left side there was a hard smooth mass, freely movable, and extending from the pelvis to three fingers' breadth above the umbilicus. On the right side a number of nodules could be felt under the skin which resembled fetal small parts. A bruit could be heard over the right side. Vaginal examination showed nothing abnormal except for the congestion of pregnancy. The cervix lay behind the symphysis. The entire cul-de-sac was filled by a mass which could be felt to the side of the uterus. The mass moved with the cervix and was soft in consistency. A five-inch suprapubic incision was made and the peritoneum opened. It was immediately apparent that they were dealing with a mass of multiple fibroids. The large mass felt in the cul-de-sac before operation was a huge fibroid partly subperitoneal and partly interstitial. Labor at term would have been impossible. It was decided that hysterectomy was the safest procedure. The right tube and ovary and the left tube were removed. The specimen showed multiple fibroids varying in size from an apple to a cocoanut. The measurements were: From above downward, 19 cm.; antero-posteriorly, 22 cm.; side to side, 13 cm. Two of the neoplasms were interstitial and the largest of these was deeply wedged into and blocked the pelvis.

Secondary Abdominal Pregnancy; Operation; Recovery.—Dr. S. M. BRICKNER reported this case. The patient was 36 years of age, the mother of one child eight

years old. Her last menstruation occurred on September 29, and was ten days overdue. She was seen on November 27. She gave a history of frequent attacks of abdominal pain, accompanied by nausea, thirst, and perspiration, and spotting. Three weeks before she had had an attack of very severe pain followed by intense prostration. Examination showed the abdomen exceedingly rigid and sensitive to touch. A mass could be made out to the right and above the uterus, extending to the umbilicus. The mass was irregular in shape and exceedingly tender. The uterus could not be made out. The diagnosis made was extrauterine pregnancy with hematocele, or secondary abdominal pregnancy. The patient was operated upon and the pelvis was found to be filled with clots and old fluid blood. To the left lay a large mass partially covered with intestines and omentum, which formed the superior portion of what was seen to be a sac. The left border of the sac was the sigmoid flexure; the posterior wall of the uterus formed its inferior wall and its right border was composed of blood clot in which the right tube was lost. At the left border of the clot and below the omentum lay the placenta. The sac was removed *en masse*. As the patient's condition did not permit of any further operative procedure the abdomen was closed. The specimen exhibited consisted of a gestation sac containing a fetus of about three months extrauterine development and amniotic fluid. The umbilical cord was attached to an irregularly shaped placenta distant about three cm. from the amniotic sac. The fetus was alive at the time of its removal, but the heart stopped beating in a few moments. The convalescence was uneventful after the first few days. This was a case of secondary abdominal pregnancy, originally a primary pregnancy of the right tube.

Dr. C. F. JELLINGHAUS discussed the papers (by invitation).

Report of a Case of Interstitial Pregnancy.—Dr. JAMES W. MARKOE reported this case. The patient was 31 years of age, and both her family and personal history were negative. Five years ago she was curetted for what was supposed to be an incomplete abortion, but no fetus was discovered. After remaining in the hospital for some time she left against the advice, but returned in a few days with high temperature, rapid pulse, and marked collapse. A diagnosis of ruptured ectopic gestation was made, but the patient's condition was so bad that it was not deemed advisable to operate. She gradually improved under conservative treatment, but was not able to leave the hospital for several months. In September, 1911, she again applied to the hospital for treatment, stating that three years previous to this time she had been delivered of a large child which was still-born. A bimanual examination showed a tumor about the size of a goose egg on the right side of the uterus and apparently connected with it. The mass was extremely tender and slightly movable. She stated that her last menstruation had taken place on July 10, so a provisional diagnosis of two months' ectopic pregnancy was made. On opening the abdomen the tumor became immediately apparent, and was seen to be directly connected with the right horn of the uterus. The left tube and ovary were congested and bound down with old and very firm adhesions, both to the intestines and to the omentum. After breaking up some of the adhesions the swollen and congested Fallopian tube, together with the left ovary, were removed. The appendix, which was bound up with the adhesions, was freed and removed by the purse-string method. A partial hysterectomy was then performed. It was deemed unadvisable to remove the entire uterus because of the possibility that old inflammatory foci on the left side might be opened up. The subsequent history of the patient was uneventful, and she was up and about on the nineteenth day. In reviewing the history of the case it seemed probable that the illness of five years ago was most likely a ruptured ectopic pregnancy, in which the hemorrhage was not very marked and the products of conception were eventually absorbed, leaving behind the dense adhesions found at the operation. The fact that in the interval an intrauterine pregnancy had occurred was of interest and showed that the conditions which prevailed to bring about the two ectopic gestations did not prevent one ovum from lodging in the normal mucous membrane of the uterine cavity. The interstitial variety of ectopic pregnancy seemed to be the least frequently met with, there being but 30 cases reported up to 1904. Since then an increasing number of cases had been reported. This was probably due to the fact that greater attention had been paid to the diagnosis of the condition. As the pregnancy developed in the wall of the uterus it might proceed to a more advanced date than in the case of the tubal varieties of ectopic gestation. For this reason a rupture of the sac was more likely to prove fatal than in the other types. It was possible that an abortion might take place either into the tube or the uterine cavity, where the growth might continue; but from the histories of the cases reported it was quite obvious that if an interstitial pregnancy was recognized an operation was necessary without delay. Unfortunately it was less easy to make such a diagnosis than in the presence of a tubal gestation, but it had been claimed that in interstitial pregnancy the amenorrhea was usually persistent, while in the tubal pregnancy more or less irregular bleeding occurred. It was important to determine in each case whether an incision of the sac was possible or whether hysterectomy was necessary.

Dr. H. N. VINEBERG said that a few years ago he had had a case of interstitial pregnancy with symptoms of an indefinite nature pointing chiefly to an obstinate constipation and general peritonitis. On examination he found a very large uterus with no definite mass in the pelvis, and while he agreed with the house surgeon, who had made a diagnosis of ectopic pregnancy, that the condition was probably due to a bursting of the products of conception, he could not convince himself that it was an ordinary case of ruptured tubal pregnancy. Upon opening the abdomen he found it filled with blood, liquor amnii, débris and a fetus of about four months, lying free among the intestines. The uterus looked as though it had had its entire fundus blown off. It was removed, together with the foreign matter in the abdominal cavity, and the patient made a good recovery. Dr. Vineberg said that he had recently had a patient with a small projection on the anterior wall of the fundus of the uterus, median to the round ligament insertion, which appeared like a small sac. This was removed and examined. Some of the pathologists stated that it was a pregnancy, and others said it was not. It was not a cyst, but a cystic mass about the size of a walnut, containing blood. These were the only instances of interstitial pregnancy that he recalled having seen in over 200 ectopic pregnancies.

Case of Fibroid Complicating a Pregnancy at the Fourth Month.—Dr. RALPH WALDO reported the case of a primipara, twenty-six years of age, who last menstruated September 7, 1911. The time that elapsed from her last menstrual period to that of the operation was eleven weeks and three days, but probably the pregnancy was not over ten or eleven weeks. The woman had been married only a few months. Her urine was normal. She sent to her family physician because of abdominal pain, and he detected a tumor in her pelvis. Shortly after this Dr. Waldo saw her and operated. He presented the specimen removed, which was a fibroid that had been situated back of the uterus and filled the pelvis and pressed on the rectum. The entire colon, especially the cecum, contained a large amount of solid matter. This patient had

been constipated for a long time; she had taken various kinds of cathartics. Dr. Waldo showed a specimen of the uterus with the fetus contained therein. An incision had been made in the cervix at one side of the cervical canal. He left one ovary in. The only thing that could have been done in this case was to take the uterus out. The patient made an uneventful recovery.

Dr. Herman J. Boldt believed that the specimens presented were the most interesting of any that had been shown in the section for some time, and he was particularly impressed with what Dr. Jellinghaus had presented. With regard to Dr. Frank's cases of primary abdominal pregnancy, he did not believe that such a condition had yet been proven, although many had been described. Some years ago Dr. Boldt had a case that he thought was unique and the specimen was sent to Dr. Welch of Baltimore for confirmation of his diagnosis. After repeated and careful examinations he reported back that it was not a case of primary abdominal pregnancy. On the placenta were two or three fimbriæ from the Fallopian tube. The point that Dr. Jellinghaus raised, and in which Dr. Boldt concurred, was that so far as the urinary fistulæ were concerned, none of his cases—and he had had several—were cured spontaneously. With regard to fecal fistulæ, they usually healed spontaneously; that was his experience in all but two instances that he had seen. The difficulty of making a diagnosis in abdominal pregnancies at present was not so great as formerly. The first case of abdominal pregnancy that it had been his privilege to see occurred in 1879. There were present at that time Drs. Goldthwaite, Pallen, Polk and Boldt. The diagnosis made was intrauterine pregnancy, and Dr. Boldt's chief, the late Dr. Pallen, purposed doing a cesarean section. The fetus lived a short time. In abdominal pregnancies the diagnosis was not so easy as might be supposed by some physicians.

Dr. H. N. Vineberg stated that Dr. Schauta had asserted at the International Congress in Budapest, in 1909, that in 100,000 cases of pregnancy in his clinic there had been only 70 cases complicated with fibroid growths, or, in other words, only seven in every 10,000 cases of pregnancy. They had just had two cases presented to them, and there were two others at present in the second Gynecological Service of Mount Sinai Hospital; he, himself, had had a case within the past couple of months which would be presented at the next meeting. It would seem, therefore, that this complication occurred more frequently here than in Vienna. The note that ran through the discussion at Budapest was one of extreme conservatism, and he had been guided by it in his practice. Every now and then cases occurred, however, in which surgery was imperative, as had been demonstrated by the cases presented to-night. Dr. Vineberg said he had had a case some years ago similar to the one reported by Dr. Jellinghaus which had not been recognized, and the patient was discharged from the hospital as suffering from an inoperable malignant growth. He had operated upon the case, and although the technique was very difficult, the placenta being very large and universally adherent to the intestines, abdominal wall, and the right pelvic wall, he was so fortunate as to remove all of the placenta, excepting the membrane. The patient made a good recovery without any complication. Regarding the healing of ureteral fistulæ, Dr. Vineberg said his experience did not tally with that of Dr. Boldt. He had seen some cases in which the fistula apparently healed, as the leakage permanently ceased and the patients were free from urinary symptoms afterwards.

Dr. Arnold Stuckmore said that, notwithstanding the energetic propaganda of the last ten years, the cases presented to-night made it very evident that they had much to learn in the diagnosis and management of extrauterine pregnancy. There was no biological reason why abdominal pregnancy should not occur more frequently. In every pregnancy it was simply a question of osmotic sustenance of the ovum in the earliest stages and vascularized nourishment in the later stages. The peritoneum sufficed for both, yet primary abdominal pregnancy had not yet been authentically established if they excluded pictorial evidences. The cases on record had all proven to be early tubal pregnancies extruded into the abdominal cavity. If they recalled the contention of those who, two years ago, advocated conservative treatment of ectopic pregnancy, the question arose as to how many cases among the non-operative would result in abdominal pregnancy with ultimate findings on the operating table such as had been detailed this evening. The very possibility of such sinister complications should make the strongest plea for prompt intervention and early interpretation of symptoms pointing to the existence of extrauterine pregnancy.

Dr. A. Ernest Gallant referred to a patient that he had presented to the Section five years ago, from whose abdomen he had removed a full term, dead child, eleven months after conception. For some days after operation the urine escaped from the vagina, later from the bowel, as loose watery stools. After some months the stools became normal, and all the urine escaped *via naturale*.

Dr. Arthur Stein said that what most interested him in these cases of myomata complicating pregnancy was the mode of operation, whether they should do an enucleation, supravaginal amputation, or total extirpation. Not long ago he had a very interesting case, and one in which it was difficult to decide upon what to do, even after the abdomen was opened, whether the enucleation of the myomata should be resorted to or a supravaginal amputation of the pregnant organ. The latter operation was performed. There were present two myomata, each of the size of a fist, on either lateral wall of the uterus, which was pregnant in the third month. Right after the operation the uterus made a few contractions and the ovum was half way expelled from the uterine cavity. Dr. Stein said he did the supravaginal amputation mainly out of fear of subsequent rupture of the uterus in case he had enucleated the myomata. However, in Dr. Waldo's case the mode of operation was a clear one from the very first start. One always must individualize in these cases. His patient was a primipara, twenty-six years of age. She made an uneventful recovery.

Dr. Robert T. Frank agreed with Dr. Boldt that most of the cases reported as primary abdominal pregnancies were really secondarily implanted on the peritoneum. All the cases reported at the meeting of the Section were unquestionably of the latter type. The three most authentic cases in the literature were those of Gallabin, Witthauer, and Hirst. Unless discovered very early, it would be impossible to distinguish between a primary and a secondary implantation. Gallabin's cases did not rupture until the tenth week. Witthauer's case, in which a six weeks' ovum was found attached to the omentum, might have been a fimbrial pregnancy torn from its primary site by retraction of the omentum. Hirst's cases, however, seemed unquestionably primary. Here a minute ovum was found embedded in the posterior layer of the broad ligament and the ovum plus the surrounding parts were widely excised and submitted to careful examination. No aberrant tubal or ovarian elements were found, and no disturbances of the ovular site had taken place. This case appeared to prove the possibility of primary abdominal implantation beyond doubt. Dr. Jellinghaus' case could not be used as an argument against the expectant treatment of ectopic gestation. The cases in which operation might safely be delayed were those of pelvic hematocele or tubal abortion, in which the process of growth had come to a standstill. In the case under discussion, had the diagnosis of extrauterine pregnancy been made, the

patient would unquestionably have been operated upon early, but the condition was not recognized.

Dr. S. M. Brickner said he had operated upon his patient because the tumor was evident, and was thought probably to be a dermoid cyst complicating pregnancy. The tumor was also rapidly increasing in size. With regard to Dr. Jellinghaus' case Dr. Brickner did not see the patient in May, but Dr. Frank saw her in August, when she appeared at the dispensary and he suspected an abdominal pregnancy. She was taken into the hospital and the examination convinced him that he was dealing with an intrauterine pregnancy, with a breech presentation. Here the mistake was made. With regard to the co-called "Dr. Brettauer's school of fallacies" five years ago Dr. Brickner suggested that cases of tubal abortion did not always require operation. Until, however, they had reached methods of diagnosis more refined than those that existed at present the same principles regarding operation would be continued as they had been following in the past, and, therefore, they would operate upon all cases of extrauterine pregnancy except large hematoceles. He asked that they assume that they were dealing with a case of tubal abortion; the abdomen would be opened, the diseased tube would be removed, as well as the contained hematoma. What was going to prevent the ovum from growing if it was alive at the time and was lying in the mass of blood clots in the pelvis?

Dr. Ralph Waldo, speaking regarding fibroids which complicated pregnancy, said that it seemed to him that there were many who believed to all practical purposes that there was a malignant disease present and required operation, but Dr. Waldo did not take this view at all. Even if the pelvis was closed by a fibroid, and if there were no uterine contractions, he would permit the woman to go to term if she would without interference; no interference should be made unless the uterus attempted to empty itself. He knew of two instances where the Porro operation had been performed and with two living children.

Case of Papilloma of the Bladder Treated by Fulguration; Demonstration of Method and Apparatus.—Dr. L. Henry Dawson Furniss reported the case of a woman seventy-two years of age, who for two years had had intermittent hemorrhages from her bladder. Kelly's cystoscope was employed to determine the nature of her trouble, which was found to be papillomata of the bladder; they were four in number, all on the left side of bladder, and in the line of the ureter. Dr. Furniss demonstrated the apparatus used. The examination and treatment was made with the patient in the knee-chest posture. After the third fulguration the urine cleared of blood for two days; then she began to bleed again and the hemorrhage was quite profuse. A suprapubic systotomy was performed, as she was unable to empty the bladder of blood clots. He was much interested to find the papillomta had sloughed out and the bleeding came from the largest one; this caused a sloughing of about one-eighth of an inch of the bladder wall. The patient was drained suprapubically. An hypostatic pneumonia developed and he feared that she was going to die because of it. Dr. Furniss gave a demonstration of the apparatus used.

Uterus and Suppurative Adnexa Removed by Panhysterectomy.—Dr. Herman J. Boldt presented this specimen, the interest of which centered in the history of the patient from whom he removed it. It was interesting to compare the symptoms with the pathological condition found at the time of operation, the specimen as such not showing anything unusual. There were present diffuse adhesions which firmly bound the pelvic organs to the surrounding pelvic walls and to the intestines. The patient was forty-nine years old, and the pyosalpinges surely must have been present a long time, probably a number of years, yet the complaint of pain in the lower abdomen and back dated back but three months. The specimen was an excellent illustration to prove that tubal inflammation might exist without causing marked inconvenience to the patient. It also demonstrated that pain, if present, was not a characteristic pain of any particular kind of pathological condition.

Myomatous Uterus Removed by Panhysterectomy. Dr. Herman J. Boldt said that the uterus was removed because of a typical bleeding, despite a previous bilateral salpingo-oophorectomy. The patient was forty years old and had been operated on, only the tubes and ovaries having been removed. In addition to the bleeding, there was a griping pain in the lower abdomen. The previous operation had left the woman with a suppurating abdominal fistula in the line of the abdominal incision. When the abdomen was opened, the reason why the previous operator had not completed the operation and was content to remove only the adnexa was readily understood; there were technical difficulties because of adhesions, and these were almost insurmountable. This was another verification of the fallacious idea that formerly existed in the minds of the profession, that for a bleeding myoma, castration sufficed to stop the bleeding. It also showed that small tumors might cause intense suffering, as was the case in this instance.

Ovarian Cyst with Twisted Pedicle and Hemorrhage into the Cyst, Complicating Pregnancy.—Dr. Herman J. Boldt reported the case of a woman, thirty-four years of age, who had had a child two and a half years ago. She was again pregnant four months. Six days previously she was seized with cramp-like pains in the left lower abdomen, and they had not entirely ceased. She asserted that since the beginning of her pregnancy she had had three such attacks, but the previous ones soon disappeared. The examination, soon after the beginning of the pain, was said to have revealed the presence of a small tumor about the size of a hen's egg. When the patient was examined by Dr. Boldt the tumor had markedly increased in size, the abdomen was sensitive to touch, and it was evident that a local peritonits was present; this was shown subsequently upon operation by the presence of intestinal and omental adhesions. The diagnosis of an ovarian cyst with a twisted pedicle and hemorrhage into the cyst was based upon the sudden occurrence of the pain, its character, the rapid increase in the size of the tumor, the intraperitoneal position of the tumor, and its close relation to the uterus. Upon operation the diagnosis was verified. There were two twists of the pedicle.

Anteflexio-Versio as a Cause of Functional Disorders of the Bladder, and a Method for Its Correction.—Dr. Arthur Stein presented this paper, in which he said that while the nature of changes which until recently had been grouped under the term "irritable bladder" had been recognized and treated, there remained a small group of disturbances which required further discussion. Under the title of "Functional Disorders of the Bladder in the Female, Simulating Cystitis," the writer had some time since reviewed the various functional disturbances of the bladder in women which did not originate in the bladder itself, but might be caused by affections of the pelvic connective tissue, by tumors, or by disturbances of the general system outside the pelvis. He had also referred to the fact that retroflexion and anteflexio-versio of the uterus might cause bladder manifestations which in all respects resembled those occurring in typical cystitis. Since the publication of that article he had directed his attention to this latter class of affections. A review of the literature of this subject showed only quite isolated references to the subject, and it was clear that the number of disturbances of the bladder which depended directly

upon an exaggerated anteversion of the uterus were very few. In 33 per cent. of all gynecological affections women complained of bladder disturbances of the most variegated kinds, and it was clear that only a small fraction of this 33 per cent. was caused by anteversion. However, it was time to call the attention of gynecologists to a treatment that he had found useful in cases of bladder disturbance due to anteversion of the uterus, although he had only a few cases to report. The treatment described was used only in such functional disorders of the bladder as were dependent upon uncomplicated, pronounced anteflexio-versio. When one recalled that a highly anteflexed and anteverted uterus, with its fundus overlapping anteriorly, permanently pressed upon the neck of the bladder and the upper part of the urethra, it was perfectly intelligible that at the point of contact there must be permanent mechanical pressure, the consequence of which would be a permanent irritation with all its sequelæ. The logical treatment was, of course, the removal of the cause of irritation. Before attempting this, however, it was necessary to exclude an affection of the bladder itself or any pathological changes in the kidneys by cystoscopic examination and chemical analysis of the urine. The idea of dislodging the uterus from an exaggerated anteflexio-versio and of retaining it in the corrected position had suggested itself to the writer and he had succeeded in doing this in four cases which he described. He had brought the uterus into its normal position and had held it there by means of a pessary by similar manipulations to those employed in the correction of a retroflexed uterus, except that the movements were reversed. The pessary was inserted as in retroflexion, but reversed so that the cross bar of the pessary was lodged in the anterior vault and the concave aspect of the ring was toward the promontory. This method had nothing to do with the one that was generally known as anteversion therapy, or with the so-called anteflexion pessary of the old school of gynecologists. He could not give any definite directions as to the shape of the pessary, as he adapted the ring to existing conditions and shaped it accordingly. In three of his cases he had used Hodge's ring, and in the fourth case he had constructed the ring by simply doubling up a hard rubber ring. In three of the cases cystoscopic examination and urinary analysis were negative. The history of the cases was practically the same. The patients complained of frequent micturition, both day and night, and all of them had undergone treatment without success. Examination in all the cases showed marked anteflexi-versio and a slight hyperemia at the neck of the bladder. After the insertion of the pessary in the manner described all of the patients showed marked improvement in the course of a few days. Three of the four cases were entirely cured of their trouble, and the fourth was greatly relieved; lack of complete success in this instance was probably due to the age of the patient, her nervous condition, and the length of time that the trouble had persisted before a proper effort had been made to relieve it. It was perfectly clear that this method was totally different from those mentioned by Fritsch and Dudley. Dudley referred to the insertion of a Hodge or Smith pessary into the vaginal vault in order to effect an elevation of the uterus, and Fritsch referred to the method of inserting a hard rubber ring into the posterior vaginal vault. The method here outlined consisted in inserting a Hodge pessary, or one especially shaped to meet existing conditions, into the *anterior* vaginal vault in an exactly reverse way to the method practised in retroflexion. The object was to get the uterus away from the bladder and to retain it in correct position.

Dr. H. N. Vineberg said that Dr. Stein had made a mistake if he thought that he was the first to have used a Hodge pessary in the reverse position for the relief of bladder disturbances occurring in women. Such an employment of the pessary had been in vogue years ago and was discarded as it became more customary to use the cystoscope in women to ascertain the cause of frequency of micturition. In some cases the existence of a pathological anteversion might cause bladder disturbances, but it could not act in that way if it was dependent upon an inflammatory condition at the base of the broad ligaments, or in Douglas' sac, drawing the cervix backward and with it the neck of the bladder. Flexion of the body of the uterus upon the cervix would not compress the neck of the bladder; if it could it ought to give rise to retention and not to incontinence. The situation of the neck of the bladder at the junction of the cervix with the body was such that it was not possible for the body of the uterus to press upon it, no matter how great the degree of anteflexion. The relief that the patients experienced could be explained by the pressure of the bar of the pessary upon the neck of the bladder, or upon the urethra adjacent to it, as in many of these cases there was weakening of the sphincter or a dilatation of the urethra, for the normal urethra served as an aid to the control of the vesical sphincter. For several years Dr. Vineberg investigated these cases of frequent micturition in women, and he had found that in the majority of cases there was more or less hyperemia and erosion of the trigonum. These slight changes were not recognizable by the Nitze cystoscope or any of its modifications, and had doubtless escaped Dr. Stein's observation. Dr. Vineberg said that he could cure these cases by the direct application of nitrate of silver solution, ten to twenty per cent. to the affected areas in the trigonum, with the patient in the knee-chest position. The customary method of applying nitrate of silver to the neck of the bladder by irrigation or instillation was valueless, as a rule. There was always some residual urine in the bladder which mixed with the inserted solution and rendered it inert.

Dr. Henry Dawson Furniss believed that malposition of the uterus had little to do with those bladder disturbances. If these cases were carefully examined it would be found that there was inflammation of the trigone or else in the urethra itself. If in the urethra the trouble would usually be in the proximal half, there more often than in the bladder portion. The use of the cystoscope seemed to have something to do with the relief of these cases. The massage of the urethra by the passage of the instrument produced good effects as well as the action of the boric acid solution which was used.

Dr. A. Ernest Gallant said that fifteen years ago he first inserted the pessary end for end, and very soon determined that the broad and curving upward part behind the symphysis lifted the trigone upward, did not compress the urethra, and elevated the whole uterus by supporting the cervix well back in the pelvis. In most of the cases there was a coincident inflammation of the trigone which must be treated by direct medication to its irritated surface.

Dr. Herman J. Boldt did not know what Dr. Stein meant by replacing the uterus in cases of anteflexio-versio. In these cases, so soon as the fingers were taken off the uterus returned to the same position previously occupied. When he spoke of bending a rubber ring, that simply was a method employed by Gehrung and one always used at Dr. Boldt's clinic. The irritation of the bladder was caused by the anteversion or the anteflexio-versio. The latter position of the uterus was the physiological position. The pessary itself never placed the uterus in proper position, but simply raised the uterus. There was no doubt but that vibration applied to the neck of the bladder gave relief in a large number of cases if there was no pathological condition present in the urethra or neck of the bladder. Overdistention of the bladder in many instances would be productive of good as well. The treatment to which Dr. Stein

had called attention was of early date. The use of the Hodge or Smith pessary did not relieve the condition any better than did the Gehrung pessary, but Dr. Boldt believed the latter held the uterus up better.

Dr. MAX ROSENTHAL said that in his experience about 75 per cent. of all the patients seen in the gynecological service of public dispensaries complained of frequent micturition. It was impossible to generalize in regard to the treatment of such cases. Many cases complicated with anteflexion were improved or cured of their frequency in micturition by simple routine treatment of tampons, douches, etc. On the other hand, cases with some organic bladder trouble required treatment directed to the bladder condition itself, without regard to the existing anteflexion.

Dr. ARTHUR STEIN, closing the discussion, said he believed that the mere lifting of the neck of the bladder had a great deal to do with the relief of the vesical disturbance in these cases. In regard to Dr. Furniss' remarks, two of his patients had been cystoscoped repeatedly by other physicians and without any relief whatever from this procedure.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 11, 1912.

Dr. WILLIAM SHANNON IN THE CHAIR.

Chronic Colitis in a Child Three Years of Age, with Deformity and Deviation of the Sigmoid Flexure.—Dr. J. FINLEY BELL presented this child. Up to the time he first saw him the patient had never had a normal bowel movement. He cried a great deal and had considerable pain and tenesmus. During the first days of the illness irrigations were tried, but were only occasionally successful, it being impossible to pass the tube higher than six inches. During the month of May his weight markedly decreased and in September the symptoms became very much worse and as many as forty movements a day were recorded. About the middle of October goat's milk was substituted for the top milk mixture and with success for a time. The attacks of colitis, however recurred and grew more frequent and more severe and were complicated by vesical irritation. The medical, hygienic, and surgical points of interest were considered in his paper.

Torsion of the Uterine Adnexa in Hernia in Infants.—Dr. ALEXIS V. MOSCHCOWITZ presented this patient, who was admitted to Mount Sinai Hospital March 25, 1911. The day previous she was seen by Dr. Heiman, who found that she had six toes on each foot; otherwise everything appeared to be normal. Nine hours before admission the child vomited and cried and the mother noticed a swelling in the left groin. A diagnosis was made of strangulated inguinal hernia. Dr. Moschcowitz saw the patient within half an hour after admission and confirmed the diagnosis, but he also made the more exact diagnosis, that the hernia contained either tube and ovary or a portion of the uterus. At operation there was found a perfect example of an inguino-superficial hernia, with the left tube and ovary twisted in one complete revolution. The baby made an uneventful recovery. He said that this form of hernia was of unusual rarity. In 1905 Damianos made an incomplete résumé upon this malady and collected twenty-four cases; additional cases reported, including his own, brought the total up to about forty. The cases of ovarian hernia occurring in children, with acute symptoms, might be divided into three groups, those having torsion of the pedicle, those with no torsion, and those in which the torsion had not been noted. The entire subject demanded discussion from three viewpoints, the presence of ovarian hernia in infants under one year, the question of torsion of the ovary, and the diagnosis. The frequency of ovarian hernia in infants under one year and in child-bearing adults was a striking phenomenon. In older children during puberty and in virgins ovarian hernia practically never occurred. The ovary descended only as far as the brim of the pelvis during intrauterine life and remained there for a year or more; its subsequent descent was due, first, to its own weight, and, secondly, to the deepening of the pelvis. This explained why in early infancy the ovary was an extrapelvic organ and was thus rendered more liable to enter a hernial sac. It seemed that congenital hernia was as frequent in the woman as in the male. A prerequisite for all torsions appeared to be a disproportion in size between the twisting body and its pedicle. This disproportion was present to a perfect degree in the ovary. However small this organ might be, it was large in comparison with the Fallopian tube. The diagnosis of twisted pedicle in ovarian hernias in infants was made from the fact of the existence of a hernia; that it was strangulated was obvious. The diagnosis of the organ or organs contained in the sac could be made by exclusion. Of the forty cases reported, the diagnosis was made by Quadflieg only; of these cases nineteen occurred on the left side and twenty on the right. The other case was not noted. With regard to the treatment, if the case was of very recent origin, gentle taxis might be tried, if this was not successful then prompt operation was indicated. Delay in operating might mean an extirpation of the organ, but even with this sacrifice the prognosis might be said to be good.

Dr. JOHN DOUGLAS said he had had two cases of hernia of the tube and ovary. One child who was admitted to the hospital did not appear to be at all sick. The diagnosis of a hernia of the tube and ovary was not thought of. The child was five years old and the diagnosis made was strangulated omentum. The baby was operated upon and made a good recovery.

Dr. HENRY W. BERG said that it was interesting to know that these herniæ of the tube and ovaries probably occurred more frequently than was generally supposed, and it was most interesting to be able to feel these in the hernial sac; the general practitioner feeling such a mass, however, naturally would think he was dealing with some neoplasm, especially since there were no symptoms of intestinal obstruction. These were not extraordinary herniæ. Dr. Berg asked whether cases of femoral hernia were more often complicated by the presence of tube and ovary in the sac rather than inguinal herniæ.

Dr. MOSCHCOWITZ replied that his two cases were inguinal herniæ and that practically all of the other cases that had been reported in the literature were of the same variety. He believed that there was but one case of the femoral variety reported.

Dr. JOHN DOUGLAS said that unless he was mistaken there had been reported in the literature, by Andrews in 1907, ninety-nine cases of hernia of the tube and ovary and the majority of them were inguinal. There were five cases of the femoral, four of the obturator, and two of the ischiatic variety.

Dr. MOSCHCOWITZ said he only referred to herniæ occurring in young infants, and not of those that occurred in adults. He referred especially to young nurslings of the female sex.

The Benefit Derived from Treatment in Birth (Erb's) Paralysis.—Dr. HENRY W. FRAUENTHAL presented this paper to call attention to the prevailing error in the minds of the general practitioners that nothing could be done for brachial plexus paralysis. This seemed strange in view of the fact that nearly all textbooks on pediatrics advised treatment for this condition. It was quite evident that Erb's paralysis was due to forcible manipulation in the process of delivering the child in most cases. It was evident that any form of traction that pulled the head and neck away from the shoulders was the exciting cause

of the lesion and as a corollary the lesion might occur with any presentation. The results of treatment depended upon the time it was begun and its kind and character. The methods of treatment advised by him were the results of his experience in the treatment of one hundred cases, in which treatment had been instituted from within forty-eight hours after birth to those in which it was begun after twenty-two years. If the baby was seen immediately after birth much benefit might be expected by approximating the ends of the lacerated nerves. This could be done by a long sleeve, extending down over the hands, up about the neck, and being attached back of the neck by means of safety pins. If the position was to be maintained, it could be done by an appliance made of soft leather, going about the body and held by laces, as shown in the photograph. The forearm could thus be held at right angles by a screw arrangement. Should a clot be present, absorption might be hastened by using a high frequency current once or twice daily for a period of five minutes. Following this he used a combined galvanic and faradic current, interrupted seventy-two times to the minute; this was accomplished by a clock arrangement in the Victor wall plate. The current should never be strong enough to produce pain sufficient to make the child cry. A mild massage of the arm and forearm might be given. After the fourth year a series of exercises was added. The author presented cases and photographs demonstrating the results of treatment, the patients running from one-half to twenty-two years of age.

Dr. Herman C. Frauenthal said that the instruction given the mothers was a very important part in the treatment of these cases of Erb's paralysis. They were instructed to place the arm between supination and pronation and to maintain it there. These patients usually came to the clinic with their hands decidedly rotated inward. When they became older the good arm was tied inside the clothes and so they were compelled to use the bad arm. Too much electricity or massage should not be used. Neuro-muscle education, however, should be employed.

Dr. Henry W. Berg said that these cases were all classed as instances of Erb's paralysis, but many were only cases of palsy which occurred immediately after birth and made spontaneous recoveries within one or two months. In an extensive obstetric practice he had seen many of these cases, cases not due to traumatism, stretching, or pulling on the part of the obstetrician. Many cases showed signs of hematoma in the axilla, or extensive traumatism, and they belonged to an entirely different group of cases. The first group were cases of birth palsies, which had a tendency to spontaneous recovery while the later group were cases of birth palsies in which the recovery was problematical. It was very important that one should be able to predict, if possible, what cases would recover in one or two months and what cases would not; in other words they should be acquainted with the type of lesion with which they were dealing. The milder type of cases occurred because of uterine pressure exerted for sometimes as long as thirty-six hours directly upon the muscles of the shoulder and arms. These were the cases in which the arm was extended over the head, often with the breech coming first, and which had been subjected for a long time to compression over the after-coming head. There was another class of cases in which the paralysis had resulted in contractures and advanced stages of atrophy; the nerves and soft parts were injured with resulting muscular and osseous atrophy. There was a lesion in the motor, sensory, and trophic nerves, all being more or less involved. It was not so much the bone itself that was injured as the trophic nerves. In these cases there resulted marked contractures of tendons and muscles. Here came in the function of the orthopedic surgeon who employed massage and electricity and who gave some relief but only up to a certain degree.

Dr. Henry W. Frauenthal said that in many instances the reaction of degeneration could not be brought out because the patients would not submit to the strength of current required. The range of motion gotten under the treatment outlined in his paper was very surprising; even though there was shortening, there was a normal range of motion.

Chronic Colitis in Child Three Years of Age, with Deformity and Deviation of Sigmoid.—Dr. J. Finley Bell read this paper, in which he recalled that in presenting the patient he had pointed out that the case suggested a number of interesting questions involving the etiology, symptomatology and diagnosis, and treatment of chronic colitis. These questions were as follows: Were all of these cases of chronic colitis due to deformity or deviation of some portion of the colon? Were such deformities and deviations always congenital or might they be the results of acute attacks of colitis of bacterial origin, the deformity being the result of severe tenesmus or excessive irrigation? Inasmuch as many cases of colitis in adults had been shown by *x*-ray diagnostic methods to have marked deformity and deviation of the colon, some of which had been improved and some cured by surgical measures whether or not they had been congenital, if they were congenital to what extent were symptoms of the condition present during infancy and childhood? Formerly the more refined attempts at diagnosis were along bacteriological lines and gave no enduring results. The bismuth test meal and enema, with *x*-ray photography, were eminently successful in this child of three years and the writer felt firmly convinced that in all cases of chronic digestive disturbance in children this procedure should be employed. In regard to treatment the points to be considered from the medical side were that the deformity could obviously not be corrected by medical measures, hence radical success depended upon the ability of the deformed intestine to functionate normally after the mucous membrane had been treated medicinally. If improvement followed such treatment would it be lasting? These conditions in any case should be considered and watched by both pediatrician and surgeon in order that the treatment might be prompt, correct, and adequate. A new field in pediatric surgery might be opened as a result of this refinement in diagnosis. In the case reported dietary medicinal measures had been tried faithfully and without avail. Irrigations had given only temporary relief. Their continued use had so impressed the little patient that he talked of but little else and was fast becoming a confirmed juvenile neurasthenic. Dr. Bell said that he would forbear speaking at length on these questions as he wished the section to discuss them.

Dr. Leon T. Le Wald demonstrated some *x*-ray plates taken of the case presented by Dr. Bell.

Dr. Joseph E. Winters said that after the age of one year it had been his experience that the cause of the appearance of mucus in the stools was milk and irrigations. The long-continued use of irrigations at any period of life would cause the persistence of mucus in the stools. The sigmoid was long in children and was very likely to become misplaced. Any child that had a colitis with mucus in the stools would do well if fed on nothing but cereals with butter and salt. He cautioned against the use of broths, milk, and eggs, and advised giving these patients only dry cereals. Irrigations should be entirely excluded from the treatment of these cases. There frequently followed an intestinal paralysis, or a chronic "ballooning" after the use of long-continued irrigations. Dr. Winters believed that every case of colitis occurring in children of one year, or at any age after this, with no other treatment except the use of cereals with butter and salt, with no irrigations, would get well in every instance and in a surprisingly short time.

Dr. Henry W. Berg said that the pictures presented

demonstrated one very important thing, namely, that the bismuth meal brought out the outline of the stomach and intestines under the *x*-ray, which was a great advantage in diagnosis. It should be remembered, however, that there was a source of error in this procedure and that was in the relative position of the patient. The pictures showed an extraordinarily large sigmoid for a child of that age. Before anyone attempted to translate pictures of the kind presented, they should be able to distinguish the normal and the abnormal and especially in these cases without any symptomatology. Dr. Berg could not conceive any method of therapy, or feeding, which would overcome such an obstruction as appeared in the pictures. Rachitic children had extraordinarily large sigmoid flexures as compared with the size of the pelvis; the pelves in these children were as a rule very shallow. The increase in the size of the spinal column was so much greater than the increase in the length of the intestinal tract that one could readily see, that if the conditions present were not pathological they might become absolutely normal in a growing child in the seventh, eighth, or ninth year. If one should temporize then either by some surgical procedure, or by irrigations, or feeding, the child might be tided over two, three, or four years: there would then be the hope that as the body grew this disproportion might be overcome and normal function occur. Of greater importance was the diagnosis and he believed that this could be made by means of the *x*-ray pictures. A cause of constipation in many cases was the increase in the length of the sigmoid itself; because of this there was not sufficient muscular power to send the stools through the sigmoid. This was a clue to the treatment. In his experience good results followed the use of enemas of soap suds with the addition of plenty of a non-irritating oil, such as sweet oil or castor oil. If they could keep the sigmoid clear of stools, they could in all probability cure the patients.

Dr. SARA WELT-KAKELS said she thought that the anomalous position of the large intestine might be an etiological factor in the production of the colitis. The descending colon and the sigmoid flexure were very long in infants; the sigmoid had multiple flexures; this and the long meso-colon permitted it to drop into the shallow infantile pelvis; this would easily result in an undue accumulation and stagnation of feces, the production of a faulty circulation, and colitis. These conditions did not remain permanently, as about the sixth or seventh year the different parts of the intestine assumed a more normal position. She suggested to Dr. Bell the use by rectum of the gastrodiaphane to learn if he could reach the place supposed to be occupied by the sigmoid flexure.

Dr. JOHN DOUGLAS spoke of another point which should be borne in mind as an etiological factor, the general musculature of the lower portion of the intestinal canal, and especially of the sigmoid flexure and the rectum: here it was deficient in tonus as compared with the rest of the intestinal tract in infants. From a medical point of view there was in the case reported a colitis; from a surgical point of view this was a case of partial volvulus. Whether the malposition was an etiological factor of the chronic colitis or not, or whether the chronic colitis was an etiological factor in the production of the malposition, Dr. Douglas did not think it was possible to say: however, one might be dependent upon the other, a sort of vicious circle. The bismuth *x*-ray was a wonderful aid not only in making a diagnosis but in indicating the treatment as well. Many cases in which malposition occurred could be tided over and so cured under proper diet which would result in an increase in the musculature of these children. In nearly all of these cases no surgical treatment was necessary. But those cases which were not cured by medical means, especially if they were losing ground, should have recourse to surgical interference. The operation was not necessarily a dangerous one. They had to consider two operations, suspension of the sigmoid (sigmoidopexy) and resection of the sigmoid. In Dr. Bell's case a sigmoidopexy might be possible and a resection might thus be avoided.

Dr. HENRY HEIMAN would not recommend the employment of soap in these cases because it irritated the delicate mucous membrane; it would be better to use the physiological salt solution. If medical treatment failed to improve the condition, and the child was losing ground, recourse should be had to surgery. Almost forty years ago Dr. A. Jacobi had called attention to these cases. In 1886 there had been described another condition which should not be confused with the one described by Dr. A. Jacobi. Among the older children there occurred an hypertrophy with dilatation of the intestinal tract, especially of the colon, and this caused a mucous colitis and constipation. One of these types would always make good recovery: this type could adjust itself; as the pelvis grew the descending colon would assume its normal size and function. Whereas in Hirschsprung's disease, with the hypertrophy and dilatation of the lower end of the colon, the patients might come to operation.

Dr. ALEXIS V. MOSCHCOWITZ thought the baby presented by Dr. Bell a very healthy looking one. In this patient the sigmoid flexure was a good sized one and, if anything in the surgical line was thought of, a resection of the sigmoid with an end to end anastomosis should be resorted to. This was rather a formidable operation, especially upon a child of three years. He thought, however, that the child was going to recover without any recourse to surgery.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

Montpelier, January 9, 1912.

ANATOMY.

1. Describe the tibia.
2. Describe the radiocarpal articulation.
3. Name the extensor muscles of the leg.
4. Describe the pericardium.
5. Give the origin and course of the pulmonary arteries.
6. Give the origin and distribution of the ulnar nerve.
7. Name the sinuses communicating with the nasal fossæ.
8. Give nerve and blood supply of rectum.
9. Describe the mesentery.
10. Give location of Cowper's glands, and state where their ducts empty.

BACTERIOLOGY.

1. Give requisites for spore formation.
2. Describe some of the vital actions of bacteria.
3. What are mordants?
4. Describe a cover-glass preparation.
5. State the effect of antitoxin on bacteria.

PHYSIOLOGY.

1. Describe ciliated epithelium and (*a*) state where it is found most abundantly; (*b*) What is the function of ciliated epithelium?
2. Name some of the bodily states which lessen the alkalinity of the blood.
3. What is the office of the columnæ carneæ?
4. What post-mortem tests should be applied to prove that air has entered the lungs of a supposedly stillborn child?
5. Describe the functions, and secretions of the stomach.
6. What is the function in digestion of (*a*) saliva, (*b*) bile?
7. How do the products of digestion find their way into the blood?
8. What is the cerebrospinal system of nerves, and to what parts of the body are its fibers chiefly distributed?
9. State where in the human economy the following substances are found: 1. fibrin; 2. mucin; 3. chondrin; 4. leucin; 5. hippuric acid.

10. Name the structures in the body whose functions are doubtful or unknown.

HYGIENE.

1. Into what general classes are foods divided? Give examples of each.
2. Describe the physiological action of alcohol.
3. What hygiene precautions should be observed by a pregnant woman?
4. If a chemical analysis of water revealed the presence of nitrates and nitrites (*a*) would this condemn it for drinking purposes? (*b*) If so, why?
5. Describe the preparation of patient, surgeon, instruments, and surroundings for operative procedures.

MATERIA MEDICA AND THERAPEUTICS.

1. How do tinctures differ from spirits? Give an example of each.
2. State the sources and dose of salicylic acid.
3. What is the best solution for hypodermyoclysis?
4. Give the therapeutic uses of boric acid.
5. Describe the therapeutic uses of glycerin.
6. Define expectorant. Mention three expectorants and state dose of each.
7. What is animal, and what vegetable charcoal? Explain their use in medicine.
8. Mention four drugs considered among the best tonics, and describe their action.
9. Name the digestive ferments used in medical practice, and give their sources and therapeutic action.
10. What are useful drugs to allay mucous irritation? Explain their action.

CHEMISTRY.

1. What relation has chemistry to the practice of medicine?
2. What are the principal varieties of thermometers? Describe their differences, and explain the transposition of the scales.
3. Give the physical and chemical properties of urine.
4. How are soaps made? What constitutes (*a*) hard soap; (*b*) soft soap; (*c*) castile soap?
5. Define specific gravity, atomic weight, reaction, reagent, and water of crystallization.

PRACTICE OF MEDICINE.

1. Give the synonyms of relapsing fever and how may it be diagnosed?
2. Name six infectious diseases in which the specific organism has been isolated and six in which it has not.
3. (*a*) What are your ideas as to complete or partial quarantine in the diseases mentioned in your reply to Question 2? (*b*) Give your reasons.
4. What have you been taught as to the medical treatment of appendicitis?
5. What may be done for non-obstructive constipation other than through medicines?
6. What are the etiological factors of jaundice?
7. Write a short article on purpura hæmorrhagica.
8. Of what use in diagnosis are blood pressure tests?
9. Give treatment for general progressive arteriosclerosis.
10. Will be to demonstrate use of certain instruments of diagnosis.

PATHOLOGY.

1. Discuss albuminuria.
2. Give pathology of nephrolithiasis.
3. What post-mortem changes are found in general paresis?
4. What is the pathology in infantile paralysis?
5. What is the theory as to the location of lesion in occupation neuroses?

OBSTETRICS.

1. (*a*) Name the generative organs of the female. (*b*) Describe briefly the uterus, giving its gross anatomy, relations to other structures in the pelvis, and its function.
2. (*a*) Define the term menstruation. (*b*) At what age does it appear? (*c*) What name is given to the period of life during which it appears? (*d*) At what age does it usually cease? (*e*) What name is given to the period of life during which it ceases?
3. (*a*) Name the bones which form the bony pelvis. (*b*) Give anteroposterior diameter of the brim. (*c*) Give transverse diameter of the outlet.
4. Upon what signs and symptoms would you base a diagnosis of pregnancy before the end of the third month?
5. (*a*) What is the normal duration of pregnancy in days? (*b*) What is the limit of its duration from a medicolegal point?
6. (*a*) How frequently would you examine the urine during pregnancy? (*b*) To what constituents, normal or abnormal, would you pay particular attention? (*c*) In the presence of edema of the face, hands and legs with albumen and casts in the urine, all of which increased in spite of proper treatment, what symptoms would lead you to bring on artificial labor?
7. Write a short article discussing the terms asepsis and antisepsis as applied to obstetrics.
8. Describe your attentions to the child from the time the head is born till it is delivered to the nurse, including the tying of the cord.
9. (*a*) What are the symptoms of impending eclampsia? (*b*) How would you treat them? (*c*) How would you treat the developed condition?
10. How would you guard against the occurrence of post-partum hemorrhage?

GYNECOLOGY.

1. Define the terms subinvolution, rectocele, pyosalpinx, cervicitis, metritis, vaginismus.
2. Describe the technique of catheterization.
3. What are the most common causes of sterility?
4. Give differential diagnosis between a small fibroid of the uterus and early pregnancy.
5. What are the dangers attending the use of the uterine sound?

SURGERY.

1. Give the symptoms of perinephritic abscess and describe the operation for its relief.
2. Diagnose tuberculosis of the hip-joint and give the treatment.
3. Mention the conditions requiring trephining of the skull. Describe the operation.
4. Diagnose gangrene, naming the different causes, and describe its management.
5. Classify ulcers of the leg and give treatment.
6. Give the symptoms and pathological anatomy of whitlow. Give the treatment.
7. Describe the symptoms of a perforating ulcer of the duodenum and give the surgical treatment.
8. Describe branchial cyst and the operation for its relief.
9. What are the symptoms of chronic ranula?
10. Mention the causes of post-operative ileus. Give the treatment for its relief.

LEGAL MEDICINE.

1. Mention the different signs of death and give methods for applying them.
2. What considerations would govern you in pronouncing death due to exposure to cold?
3. Describe the post-mortem appearances in death due to strangulation.
4. Mention means for detecting malingering in alleged cases of injury.
5. Differentiate the following: Hallucination, illusion, delusion, paranoia, paresis.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

Montpelier, January 9, 1912.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 230; or Gray's "Anatomy" (1910), page 231.
2. See Cunningham's "Anatomy" (1909), page 283; or Gray's "Anatomy" (1910), page 314.
3. *Extensor muscles of the leg:* The muscles forming the quadriceps extensor (vastus externus, vastus internus, crureus, and rectus femoris).
4. See Cunningham's "Anatomy" (1909), page 793; or Gray's "Anatomy" (1910), page 551.
5. See Cunningham's "Anatomy" (1909), page 795; or Gray's "Anatomy" (1910), page 577.
6. See Cunningham's "Anatomy" (1909), page 629; or Gray's "Anatomy" (1910), page 1039.
7. *Sinuses communicating with the nasal fossa:* Sphenoidal sinus, anterior and posterior ethmoidal sinuses, maxillary sinus (antrum of Highmore), and frontal sinus.
8. RECTUM. *Nerve supply:* From sacral plexus, fourth sacral, and inferior hemorrhoidal nerves, and from inferior mesenteric and hypogastric plexuses. *Blood supply:* Superior hemorrhoidal, middle hemorrhoidal, and inferior hemorrhoidal arteries and veins.

9. See Cunningham's "Anatomy" (1909), page 1071; or Gray's "Anatomy" (1910), page 1265.

10. *Cowper's glands* are situated between the two layers of the deep perineal fascia, on either side of the membranous urethra. Their ducts open on the floor of the bulbous portion of the urethra about one inch from the glands.

BACTERIOLOGY.

1. "*The conditions under which bacteria form spores* vary with the nature of the organism. The bacillus of anthrax, as a rule, forms spores only when in contact with free oxygen; the tetanus bacillus, on the other hand, and the anaerobes in general form spores in the entire absence of oxygen. A suitable temperature is essential to the formation of spores; the anthrax bacillus forms spores most abundantly at about 30° to 32° C., and will not produce spores below a temperature of about 12°. Lack of food is apparently not an adequate stimulus to spore formation. In all cases a period of uninterrupted vegetative multiplication precedes the appearance of spores, and the conditions necessary for the production of spores seem to arrive simultaneously for most of the cells in a culture. In at least some cases the cause of spore formation is to be found in an accumulation of metabolic products in the culture; these may perhaps be acids, perhaps other injurious compounds."—(Jordan's *Bacteriology.*)

2. *Some of the vital actions of bacteria:* Fermentation; putrefaction; production of colors, gases, acids, alkalies, odors, nitrites; liquefaction of gelatin; phosphorescence; and production of diseases.

3. *Mordants* are substances used in staining to make the dye or stain hold fast (or "bite").

4. See French's "Practice of Medicine" (1910), page 1257.

5. An antitoxin does not absolutely destroy the toxins produced by the bacteria, but rather nullifies their action. It is believed that the antitoxin and the toxin enter into a sort of loose chemical combination, and that so long as this combination exists the poisonous properties of the toxins are held in abeyance.

PHYSIOLOGY.

1. *Ciliated epithelium* is a form of epithelium consisting of simple columnar, or stratified columnar cells, on the free or exposed surface of which are a number of hair-like processes called cilia. These possess power of wave-like motion in one direction only. Ciliated epithelium is found in the greater part of the respiratory tract (except the vocal cords), Fallopian tubes, upper part of uterus, Eustachian tube, part of the excretory duct of the testicle, ventricles of the brain, and central canal of the spinal cord. Its *function* is motion and protection.

2. *The alkalinity of the blood may be lessened by:* (1) Great muscular exertion, (2) anemia, (3) rheumatism, (4) fevers, (5) diabetes, (6) cholera, and (7) uremic conditions.

3. *The office of the columnæ carneæ* is: To prevent too great dilatation of the ventricles; to regulate their contraction; and to prevent the auriculo-ventricular valves from being turned into the auricles.

4. If respiration has taken place, the lungs will float on being put into water; if respiration has not taken place, the lungs will sink. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration, they fill the whole cavity.

5. *The functions of the stomach* are: (1) The reception of food; (2) the secretion of gastric juice; (3) the thorough mixing of the food with the gastric juice; (4) the digestion of proteids; (5) and the absorption of such part of the food as is ready for absorption.

Gastric juice is a thin, colorless fluid; acid in reaction; specific gravity about 1002 to 1010; and containing about 1 per cent. of solids. The daily secretion amounts to 10 or 15 pints. It contains: Water, pepsin, rennin, hydrochloric acid, chlorides (of calcium, sodium, and potassium), and phosphates (of calcium, magnesium, and iron). Its function is to change proteids into proteoses and peptones, and to curdle the casein of milk; it is also slightly antiseptic, and inverts cane sugar into dextrose and levulose.

The pepsin and rennin come from the central cells in the cardiac glands and from the cells of the pyloric glands. In both of these glands the pepsin preexists as pepsinogen. The hydrochloric acid is formed by the oxyntic cells. Just how a free acid is formed from the alkaline blood and lymph is not known. It has been suggested that it may occur as follows:

(1) $2Na_2HPO_4 + 3CaCl_2 = Ca_3(PO_4)_2 + 4NaCl + 2HCl$

or (2) $Na_2HPO_4 + H_2O + CO_2 = NaHCO_3 + NaH_2PO_4$;

and then $NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl$.

6. The *saliva* begins to change the starches into dextrin and sugar; and the *bile* assists in the emulsification and saponification of fats, aids in the absorption of fats, promotes peristalsis, and also inhibits peptic digestion.

7. The products of digestion find their way into the blood by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unite to form the portal vein; and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids and sugar go by way of the portal vein to the ascending vena cava; and the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

8. *The cerebrospinal system of nerves* consists of the nerves which are attached to the cerebrospinal axis (or such nerves as have their origin in the cerebrum, medulla, and spinal cord).

Its fibers are chiefly distributed to the voluntary muscles, the organs of special sense, skin, and other parts endowed with sensibility.

9. *Fibrin* is found in the blood and lymph; *mucin*, in saliva and synovial fluid; *chondrin*, in cartilage and bone; *leucin*, in spleen and pancreas; *hippuric acid*, in the urine.

10. *The functions of the following are doubtful, or unknown:* Spleen, thyroid, thymus, parathyroids, carotid and coccygeal glands, and the pituitary body.

HYGIENE.

1. *Foods are divided into:*

I. Inorganic. { Water. / Salts.

II. Organic. { Non-nitrogenous. { Carbohydrates. / Fats. } / Nitrogenous—Proteids. }

Example of each: *Carbohydrate*, sugar; *Fat*, fat of meat; *Proteid*, flesh of animals; *Salt*, sodium of chloride.

2. PHYSIOLOGICAL ACTION OF ALCOHOL. *Nervous system:* Alcohol is first a powerful excitant, afterward a depressant; it increases the reflex activity of spinal cord, muscles, and nerves; in large doses it produces lack of co-ordination. *Circulatory system:* It stimulates the heart muscle and increases the rapidity and force of the heart beat; there is a rise of arterial pressure. *Respiration* is stimulated by small doses, and decreased by large ones. *Temperature:* Alcohol produces a sensation of warmth, and warms the extremities by causing the heart to pump hot blood from the center of the body to the cold parts. If used in excess the temperature rapidly falls, owing to increase of heat radiation and to depression of vital power. *Bodily metabolism:* Elimination of CO_2 is generally increased; the effect on absorption of O is not known. It adds force but not tissue to the body. *Elimination:* It is largely burnt up in the body, but in excessive doses it is eliminated by the breath, skin, kidneys, and intestines. *Digestion* is aided by moderate doses, but is disordered by large amounts. (From Hare's *Therapeutics.*)

3. *Hygienic precautions to be observed by a pregnant woman:* She requires pure air, mild outdoor exercise when possible, clothing free from constrictions of all kinds; cold and draughts must be avoided; warm baths should be taken at least three times a week; during the later weeks of pregnancy the nipples should be kept scrupulously clean, free from pressure, and softened by applications of borated vaselin or cocoa butter; sleep and ample rest are requisite; coitus should be avoided; crowded apartments, theaters, churches, etc., should be shunned; constipation should be corrected, and the urine should be examined every two weeks. (From Kings' *Obstetrics.*)

4. *Nitrates* are generally due to the oxidation of organic matter of animal origin.

Nitrites generally indicate sewage contamination. The presence of nitrites should condemn the water; so should a marked amount of nitrates.

5. "The *operating-room* should be as devoid of furnishings, hangings, etc., as possible, and should be freely ventilated, light, and warm. Its floor and walls should be frequently scrubbed and washed with antiseptics. Windows when open should be properly screened to prevent the ingress of insects. *Instruments* should be boiled for twenty minutes in 5 per cent. soda solution. *Ligatures* (catgut) may be prepared by any of the usual methods: boiling in alcohol, boiling in cumol, the formalin method, or soaking in potassium iodide-iodine solution. Silk and silk-worm-gut should be repeatedly boiled in saline solution. All *dressings* should be sterilized by steam or prolonged immersion in bichloride solution 1:2000. Paraphernalia of the operating-room should be wiped with a cloth dipped in bichloride solution, 1:1000, shortly before

operation. *Patient* should, if possible, receive a full bath and a cathartic the night before operation. The operation site should be scrubbed with soap and warm water and an antiseptic dressing applied, which should be removed just before operation, the site again washed with soap and water, followed by alcohol, ether, and bichloride solution 1:2000. The whole patient should be covered by a sterilized sheet or sterilized towels securely pinned together. The *surgeon* and assistants should don sterilized caps and masks. The hands and forearms should be thoroughly scrubbed with soap and running hot water for five minutes, special attention being paid to the nails, and the subungual space cleaned by a wooden stick, then immersed in alcohol followed by bichloride 1:2000 for three minutes, or in a saturated potassium permanganate solution, with or without the addition of bichloride 1:2000. This may remain on the hands during the operation, or the hands may at once be decolorized by saturated solution of oxalic acid, after which they are rinsed in sterile saline or a dilute bichloride solution 1:3000. The surgeon should then don a sterilized gown. All subsequent dressings should be done under antiseptic precautions as regards wound, dressings, instruments, and hands." (Scott's *State Board Physiology and Hygiene.*)

MATERIA MEDICA AND THERAPEUTICS.

1. *Tinctures* are solutions of non-volatile substances in alcohol or diluted alcohol. *Spirits* are solutions of volatile substances in alcohol or diluted alcohol. *Examples:* Tincture of aconite; spirit of nitrous ether.

2. *Source of salicylic acid:* Certain plants (gaultheria and spiræa); it is also prepared synthetically from phenol and carbon dioxide, or from oil of wintergreen and solution of potash. *Dose,* 7 grains.

3. *The best solution for hypodermoclysis* is a physiological solution of sodium chloride (about 0.6 per cent.)

4. *Therapeutic uses of boric acid:* It is used as a mild antiseptic; sometimes it is given to correct fermentative dyspepsia, and also in cystitis.

5. *Therapeutic uses of glycerin:* As an emollient, laxative, and as a vehicle for other medicaments; it is sometimes given for hepatic and nephritic calculi, for trichinosis, and in vomiting of pregnancy.

6. An *expectorant* is an agent which modifies the secretion of the broncho-pulmonary mucous membrane, and promotes its expulsion. *Examples:* Fluidextract of squill, dose 2 minims; fluidextract of senega, dose 10 to 20 minims; tartar emetic, dose gr. 1/10.

7. "*Animal charcoal,* or bone-black, is prepared by burning bones in closed iron cylinders. It is composed of carbon and calcium carbonate and phosphate. *Purified animal charcoal* is bone-black from which the earthy salts have been removed by hydrochloric acid. *Vegetable charcoal or wood charcoal* is prepared from soft wood and is finely powdered. The dose is from ½ to 2 drams.

"Charcoal has the property of absorbing many times its own volume of gases or vapors. Owing to the oxygen condensed within its pores it has considerable oxidizing power, which may be utilized to destroy offensive gases, like hydrogen sulphid, and to hasten the decomposition of organic matter. Thorough wetting destroys its activity. As it is not absorbed when taken internally it exerts no specific action on the body. Charcoal is employed chiefly as an absorbent and a deodorant. In the form of a poultice it was at one time a favorite application for foul ulcers, but it has been largely displaced by more cleanly dressings. While it is a satisfactory agent for deodorizing fecal discharges it has less disintegrating action than dry earth. Internally it is sometimes useful as an absorbent in flatulent dyspepsia. It may be given as a powder or in lozenges. Animal charcoal is not used for medicinal purposes, but it is largely employed by chemists for removing coloring-matter from alkaloids. It was formerly regarded as an excellent filtering medium for drinking-water, but it has been shown to be unsafe for this purpose, since by adding phosphates and nitrates to the water it actually favors the development of bacteria." (Stevens' *Materia Medica,* etc.)

8. *Four tonics:* Strychnine, iron, quinine, and arsenic.

Strychnine raises the blood pressure, stimulates the medulla and spinal cord, sharpens the special sense organs, quickens and strengthens the respirations, increases the appetite and gastric secretions. *Iron* may increase the hemoglobin and number of red blood corpuscles. *Quinine* sharpens the appetite and promotes gastric peristalsis. *Arsenic* increases the pulse rate and the number of red-blood corpuscles, stimulates the nervous system, increases the appetite and favors digestion.

9. There are only two *official* digestive ferments, viz., pepsin and pancreatin. Trypsin is also a digestive ferment.

Pepsin is indicated as an aid to gastric digestion in gastralgia, gastric cancer and ulcer, atonic dyspepsia, and the vomiting of pregnancy.

Pancreatin is indicated as an aid to digestion, and for the predigestion of food, in convalescence, in wasting diseases, and in intestinal dyspepsia.

10. Demulcents and emollients are useful drugs to allay mucous irritation. Their chief action is mechanical and protective; they may also aid in subduing pain. The chief are: Flaxseed, acacia, tragacanth, marshmallow, licorice, white of egg, oils of various kinds, petrolatum, and glycerin.

CHEMISTRY.

1. Since chemistry enters into almost every branch of medical science,a knowledge of chemistry is of the very first importance to the practitioner of medicine; physiology and its many problems are largely based on chemistry; toxicology and materia medica cannot be understood without chemistry; bacteriology, pathology, the newer studies in immunity, problems in diagnosis, hygiene, antisepsis, etc., depend to a great extent on chemistry.

2. "Thermometers are instruments for the measurement of temperature. They are usually glass tubes having a bulb blown at one end and closed at the other, the bulb and part of the tube being filled with mercury or with alcohol, whose contraction or expansion indicates a fall or rise of temperature. . . . In every thermometer there are two fixed points, determined by experiment. The lower, or freezing point, is fixed by immersing the instrument in melting ice, and marking the level of the mercury in the tube upon the glass when it has become stationary. The higher, or boiling point, is similarly fixed by suspending the instrument in the steam from boiling water. The instrument is then graduated according to one of three scales: the Celsius, or Centigrade, the Fahrenheit, and the Réaumur. The freezing point is marked 0° in the Centigrade and Réaumur scales, and 32° in the Fahrenheit. The boiling point is marked 100° in the Centigrade, 212° in the Fahrenheit, and 80° in the Réaumur scale. The space between the fixed points is divided into 100 equal degrees in the Centigrade scale, into 180 in the Fahrenheit, and into 80° in the Réaumur." (Witthaus' *Manual of Chemistry.*)

To convert the readings of one scale into terms of the others:

$$C^\circ = \frac{5}{9}(F - 32) \qquad C^\circ = \frac{5}{4}R^\circ$$

$$F^\circ = \frac{9}{5}C^\circ + 32 \qquad F^\circ = \frac{9}{4}R^\circ + 32$$

$$R = \frac{4}{5}C^\circ \qquad R^\circ = \frac{4}{9}(F^\circ - 32)$$

3. *Urine* is a fluid, of a yellowish color, acid reaction, specific gravity of about 1015 to 1025, characteristic odor. It is made up of: water, urea, uric acid, hippuric acid, creatinin, creatin, xanthin, pigments; chlorides, sulphates, and phosphates (of calcium, sodium, potassium, magnesium, and ammonium).

4. Soaps are made by the action of an alkali on a fat. A *hard* soap is made with sodium hydroxide; a *soft* soap, with potassium hydroxide; *Castile* soap is a sodium soap made from olive oil.

5. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of a like volume of some other substances taken as a standard, under similar conditions of temperature and pressure.

Atomic weight is the weight of an atom of an element as compared with the weight of an atom of hydrogen.

Reaction is the expression (by means of symbols, numbers and signs) of a chemical action. It is also used with reference to the action of substances upon certain organic pigments.

Reagent is a substance (or agent) used to bring about a reaction.

Water of crystallization. "Many substances, upon assuming the crystalline form, take with them a definite number of molecules of water, which are necessary to the maintenance of the peculiar form, and frequently the color, but which in no way modify the chemical properties of the substance. It is called water of crystallization." (Witthaus' *Essentials of Chemistry.*)

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), page 128; or Osler's "Practice of Medicine" (1909), page 109.

2. *Six infectious diseases in which the specific organism*

has been isolated: Typhoid fever, diphtheria, tuberculosis, syphilis, erysipelas, plague.

Stir in which it has not: Rheumatism, scarlet fever, measles, mumps, dengue, typhus fever.

3. See index to French's or Osler's "Practice of Medicine," under heading of these diseases.

4. See French's "Practice of Medicine" (1910), page 805; or Osler's "Practice of Medicine" (1909), page 518.

5. See French's "Practice of Medicine" (1910), page 824; or Osler's "Practice of Medicine" (1909), page 527.

6. See French's "Practice of Medicine" (1910), page 800; or Osler's "Practice of Medicine" (1909), page 534.

7. See French's "Practice of Medicine" (1910), page 538; or Osler's "Practice of Medicine" (1909), page 745.

8. See French's "Practice of Medicine" (1910), page 10.

9. See French's "Practice of Medicine" (1910), page 644; or Osler's "Practice of Medicine" (1909), page 853.

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), page 898; or Osler's "Practice of Medicine" (1909), page 672.

2. See French's "Practice of Medicine" (1910), page 938; or Osler's "Practice of Medicine" (1909), page 700.

3. See French's "Practice of Medicine" (1910), page 1128; or Osler's "Practice of Medicine" (1909), page 896.

4. See French's "Practice of Medicine" (1910), page 1118; or Osler's "Practice of Medicine" (1909), page 915.

5. In *occupation neuroses*, "the nature of the disorder is not known; it has been variously ascribed to disorders of the muscles, the peripheral nerves, and the cerebral cortex; it is likely that much of the disorder emanates from the cells of the cerebral cortex, which perhaps become exhausted from the necessarily prolonged effort to innervate the muscles; but whether this is the whole process is doubtful." (Kelly's *Practice of Medicine.*)

OBSTETRICS.

1. See Jellett's "Midwifery" (1910), pages 30 and 39; or Hirst's "Obstetrics" (1909), pages 30 and 40.

2. (*a*) Menstruation is the series of phenomena which occur periodically in the non-pregnant adult female from puberty to the menopause, consisting chiefly in a bloody discharge from the genital canal, and accompanied by various physical and psychical manifestations.

(*b*) It generally appears at about the fourteenth year.

(*c*) Menacme.

(*d*) It usually ceases at about 45 to 50 years of age.

(*e*) This period is called the *menopause.*

3. (*a*) Two ossa innominata (each consisting of ilium, ischium, and pubic bone), sacrum, and coccyx.

(*b*) The antero-posterior diameter of the brim is about 4 or 4¼ inches.

(*c*) The transverse diameter of the outlet is about 4 or 4½ inches.

4. See Jellett's "Midwifery" (1910), page 241; or Hirst's "Obstetrics" (1909), page 204.

5. (*a*) The normal duration of pregnancy is about 278 or 280 days.

(*b*) In this country there are no legal limits to the duration of pregnancy. Each case must be taken on its own merits, and will probably depend upon many factors, such as: (1) The special conditions in each case; (2) the truthfulness or untruthfulness of the witness and her lawyers; (3) the gullibility of the jury.

6. (*a*) In the early period, about once in two weeks; later, once a week, or even twice a week.

(*b*) I would pay particular attention to the amount of solids excreted (particularly to the urea), also to the presence of albumin, casts, and sugar.

(*c*) See Jellett's "Midwifery" (1910), pages 502 and 617; or Hirst's "Obstetrics" (1909), pages 249 and 630.

7. See Jellett's "Midwifery" (1910), page 139; or Hirst's "Obstetrics" (1909), pages 773 and 712.

8. See Jellett's "Midwifery" (1910), page 1143; or Hirst's "Obstetrics" (1909), pages 344 and 373.

9. See Jellett's "Midwifery" (1910), pages 617 and 620; or Hirst's "Obstetrics" (1909), pages 630 and 641.

10. See Jellett's "Midwifery" (1910), pages 891 and 350; or Hirst's "Obstetrics" (1909), page 339.

GYNECOLOGY.

1. *Subinvolution* is failure on the part of the uterus to "involute" after childbirth; the uterus remains abnormally large.

Rectocele is a bulging (of the rectum) into the posterior vaginal wall, generally due to relaxed tissues or lacerated perineum.

Pyosalpinx is a purulent inflammation of the Fallopian tube.

Cervicitis is inflammation of the cervix of the uterus.

Metritis is inflammation of the wall of the body of the uterus.

Vaginismus is a condition characterized by painful and spasmodic contraction of the vaginal orifice, more or less preventing coitus.

2. See Hirst's "Obstetrics" (1909), page 370.

3. *The most common causes of sterility* are: Gonorrhea; malformation, maldevelopment or absence of any part of the genital tract; obesity; alcoholism; fistulæ; traumatisms; dyspareunia; pelvic inflammations; lacerations; anemia; incompatibility; frequently the cause is to be found in the male.

4. To differentiate a small uterine fibroid from early pregnancy the following table (from Dudley's "Gynecology") will help; but the course of time will *prove the diagnosis.*

PREGNANCY.	FIBROID.
1. History of pregnancy.	1. Absent.
2. Uterus soft and elastic.	2. Usually irregular in form and harder.
3. Consistence varies with uterine contractions.	3. Uterine contractions not marked—very important sign.
4. Cervix soft.	4. Hard or not so soft.
5. Regular and uniform increase in size of uterus.	5. Growth slower and irregular.
6. Later, ballottement, fetal heart-tones.	6. Absent.
7. Palpation of fetus.	7. Palpation of myoma.

5. The dangers attending the use of the uterine sound are: Sepsis, perforation, hemorrhage, and induction of abortion.

SURGERY.

1. See Rose and Carless' "Surgery" (1911), page 1192; or Da Costa's "Surgery" (1911), pages 147, 1285, and 152.

2. See Rose and Carless' "Surgery" (1911), pages 683 and 684; or Da Costa's "Surgery" (1911), pages 635 and 636.

3. *Indications for trephining:* "Intracranial hemorrhage; abscess; fracture; foreign body; evacuation of cerebrospinal fluid through the lateral ventricle; as a preliminary step to osteoplastic resection and to linear craniectomy; epilepsy; bullet and other wounds; small tumors; drainage of frontal sinus; drainage of mastoid antrum and cells; thrombosis of venous sinuses." (Bickham's *Operative Surgery.*) And see Rose and Carless' "Surgery" (1911), page 759; or Da Costa's "Surgery" (1911), page 842.

4. See Rose and Carless' "Surgery" (1911), pages 103 to 119; or Da Costa's "Surgery" (1911), pages 179 to 198.

5. See Da Costa's "Surgery" (1911), pages 168 and 169.

6. See Rose and Carless' "Surgery" (1911), page 247; or Da Costa's "Surgery" (1911), pages 738 and 740.

7. See Rose and Carless' "Surgery" (1911), pages 1018 and 1054; or Da Costa's "Surgery" (1911), page 980.

8. See Rose and Carless' "Surgery" (1911), page 897; or Da Costa's "Surgery" (1911), page 395.

9. See Rose and Carless' "Surgery" (1911), page 856; or Da Costa's "Surgery" (1911), page 921.

10. See Rose and Carless' "Surgery" (1911), pages 1127 and 1134; or Da Costa's "Surgery" (1911), pages 969 and 974.

LEGAL MEDICINE.

1. *Phenomena and signs of death*, are: The complete and permanent cessation of circulation and respiration, rigor mortis, loss of body heat, pallor of the body, putrefaction.

For methods of applying the tests, see a good text-book on medical jurisprudence.

2. *Prolonged exposure to cold* causes first a lividity and then a whiteness of the extremities, ears, nose, and cheeks; this may be followed by gangrene. Pain, depression, stiffness, and congestion follow; stupor, coma, and death may supervene.

Post-mortem appearances: The skin is pale and waxy, with irregular dusky, reddish patches; the superficial parts are bloodless, while the viscera, including the brain, are congested; the heart and large vessels leading from it are full of blood, and the blood is of a brighter red color than usual.

The post-mortem changes in death from freezing are not sufficiently characteristic to justify a positive opinion on the subject. But if the body were found putrefied, it would be evidence that death was not due to freezing, for intense cold hinders putrefaction. So, too, the posture of the body might afford some aid; if the body is found

in a crouching posture, death was *probably* due to freezing, as that attitude is characteristic.

3. In *death by strangulation:* The blood is of a dark color, owing to complete reduction of the hemoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty or nearly so. The lungs may be congested, but are often pallid and anemic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anemic or more or less congested. Special signs characterize special modes of causation of asphyxia.—(From Quain's *Dictionary of Medicine.*)

4. A *malingerer* is one who pretends to be ill when he is not. To aid in the discovery: Try to ascertain if there is any motive in such claim to be ill; make frequent and thorough examinations; the examiner should be well read and expert; instruments of precision and anesthetics should be used if necessary; malingerers are apt to overdo their part.

5. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression received through one of the senses. An *hallucination* is the same as an illusion but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion.* If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion.* If a person fancied he heard a voice when there was nothing at all to be heard that would be an *hallucination.*

Paranoia "is a form of insanity which comes especially under the class of degenerative diseases. It is essentially characterized by a delusion or delusions of a fixed and systematized character. They are usually indeed of one kind, and the disease has perhaps for this reason been called monomania. This is, however, an unfortunate term, as we find this symptom not infrequently in other forms of insanity, as melancholia, where we always observe decidedly fixed ideas of depression. The main fundamental characteristic of this disease is a delusion which has become a part of the belief of the individual, and which he believes himself able to explain and defend."—(Witthaus and Becker's *Medical Jurisprudence*, etc.)

Paresis is partial or general paralysis.

Effect of Excessive Heat on Infants.—Liebman at the International Congress for the Protection of Infants called attention to the effect of extremely hot weather on young children. An intensely hot summer is one in which infantile mortality is much increased. This is due not to the effect of digestive disturbances due to vicious feeding but to the direct effect of the heat, a sort of heatstroke. The condition is characterized by the rapidity of the fatal outcome, the presence of convulsions, and absence of digestive troubles. Bottle-fed babies, having less resistance, are particularly exposed to this condition. The only preventive treatment is to take the children away from the heat, place them in cool places, especially in cellars. Also the clothing should be very light. In the discussion Liegert stated that at Cologne it was observed that certain houses were fatal to infants, and in them the temperature was always high. One should take account of the direct effects of extreme heat and not attribute too much to errors of feeding in infants.—*Journal de Médecine de Bordeaux.*

Value of the Albumin Reaction in Sputum.—G. P. Goggia has tested the diagnostic value of the albumin reaction of sputum in tuberculosis. He finds that all sputum contains more or less albuminoid substances and these substances may be revealed by tests. Part of them are in the fluid and part are represented by the histological elements. In those sputa which contain albuminoids in the aqueous portion one may get a true albumin reaction. The more pus there is present in the sputum the richer will it be in albuminoids, but this has little value as a test. When there is little pus the albumin reaction is more diagnostic. Only in these cases has the albumin reaction a diagnostic value in early tuberculosis, and it thus excludes the diagnosis of pulmonary emphysema.—*Annali dell' Instituto Maragliano.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended February 16, 1912.

FAILURE OF THE COLON TO ROTATE.*

BY CHARLES H. MAYO, M.D.,

ROCHESTER, MINN.

A CERTAIN percentage of surgical operations are performed for the relief or correction of conditions due directly or indirectly to some congenital deformity or faulty development of the fetus. The greater number of these defects are usually distressingly apparent, and in these cases surgical aid is sought early with the hope that the deformity may be reconstructed and reduced to a state as normal as possible. The common afflictions, such as harelip, clubfoot, imperforate anus, anomalies of external genitalia, etc., usually come under the surgeon's care in infancy or early childhood; but within the abdomen congenital deformities are so efficiently concealed that only a small percentage of them are found until adult life is reached, and then only at operation or autopsy. The various phases resulting from non-obliteration of the vitelline duct, dermoid cysts, anomalies of the female genitalia, variations in the position and relationship of the large intestine, are familiar examples of these conditions.

The relative rarity of these obscure intraabdominal abnormalities and the fact that they so infrequently give rise to definite symptoms explain in part why a diagnosis is so seldom made when trouble occurs. However, within recent years the increase in the number of explorations for obscure abdominal conditions, and the enormous increase in operations performed on the intestine for a definite purpose, make it imperative that the surgeon should become familiar with anomalies of the abdominal contents, having in mind the possible conditions.

In case of the large bowel for example, there may be complete transposition of the viscera. The whole of the colon may be on the left side of the abdomen through failure to rotate in its early development. A partial rotation may leave the cecum at any point between the normal and the right under-liver position, or the left umbilical position and the left pelvic. Because of congenital or acquired openings in the diaphragm much of the colon with other abdominal viscera may be located in the pleural cavity.

The primitive alimentary canal is a midline vertical tube connected to the spine by a fold of peritoneum. Later the primitive stomach appears as a bulbous enlargement of it in the upper abdomen, while the lower portion retains its connection with the spine and becomes the descending colon and sigmoid as well as the left part of the transverse colon. Their blood supply is derived from the inferior mesenteric artery. In the portion of the primitive gut between this part of the colon and the stomach bulb, another small bulbous enlargement appears near the central portion, which indicates the developing cecum. This distal portion, or colonic section, enlarges slowly in comparison with the proximal or small intestinal area, and all of this midsection has a common mesentery supplied by the superior mesenteric artery.

With the rapid growth of the small intestine and the slow growth of the large intestine, a rotation of the mesentery occurs, and the colon being wholly on the left side of the spine, rotates about the mesenteric axis, the cecum passing across the duodenum to the right hepatic position and descending to the right iliac fossa. By the eleventh or twelfth week the cecum lies immediately beneath the liver and to the left of the midline. It travels to the right, crossing the descending duodenum, and at the fourth month is found lying on the right side just beneath the liver. From this position it descends slowly to its adult position, which it usually approaches toward the end of fetal life, but it may not actually reach this point until some time after birth. (Cunningham.) While ordinarily the rotation may be nearly or quite completed before birth, it may fail to occur at all, or it may be arrested temporarily or permanently in any position during its circuit.

In the event of any of these abnormalities, the following complications may arise: (1) Failure to find the appendix at operation, or it may be found in the rectrocecal or in the hepatic position, or it may be in the superior midline adherent to the gall-bladder, duodenum, or stomach; or again it may be found to the left of the umbilicus or in the middle of the left pelvis. (2) In the complete failure of the colon to rotate, the duodenum is movable, it has a mesentery, and merges directly into the jejunum uncovered by the transverse colon or its mesentery. The condition should be considered *probable* when no colon is found on the right side, and *positive* if the duodenum is found as described above. (3) Failure of the colon to rotate should be considered as a possible cause in cases of obscure inflammatory conditions in the left or middle pelvis, or in the left iliac fossa, particularly in the young individual. In the middle-aged and older individual, with left-sided inflammations, it should be considered a possible condition and should be differentiated from malignancy, diverticulitis, and complete transposition of the viscera.

Approximately 300 cases of complete transposition of the abdominal viscera have been reported in the literature. In six cases which were observed at St. Mary's Hospital, three were operated upon for left-sided appendicitis—two with acute abscess.

*Read before the Western Surgical and Gynecological Association, Kansas City, Dec. 10, 1911.

Very little is found in the literature as regards failure of the colon to rotate, although it is undoubtedly a condition which should be considered as more frequent than complete transposition. The condition will be found described under various anomalies of the duodenum as well as of the colon. We have observed five of these cases during the past two years, and in only one of the cases was the abnormality diagnosed before operation. The points noted in this case were: (1) Difference in colonic percussion note over the whole of the left side; (2) general intestinal distention, and during attacks distress in lower transverse abdomen; (3) irritation of the stomach and obstipation of a pelvic appendicitis. The conditions were not acute at the time of observation, as they were in two of the others, and after a forced, thorough intestinal evacuation a bismuth acacia soup was administered and a series of interval radiographs were made which pictured the abnormal bowel condition as disclosed by its transit.

While the condition had been previously observed in the clinic at St. Mary's Hospital in the course of routine abdominal operations, some of the puzzling features in connection with the following five cases have influenced us to report them somewhat in detail. These cases are not of the partial rotation type, but rather of complete failure of the cecum to leave its earliest situation on the left iliac side.

Dr. G. E. Armstrong and Mr. John D. Malcolm,* in two comparatively recent articles, have taken up the subject from the standpoint of abnormalities, reporting cases observed in the course of operations.

Case I.—(37121), C. O., male, aged nine years. Consultation April 29, 1910. Previous history not important. When first seen patient had been suffering for twenty-four hours from severe cramp-like pains across the lower abdomen, with no definite localization. Vomiting, fever, and rigidity gave evidence of an acute inflammatory process, probably appendicitis, and immediate operation was advised. Operation April 29, 1910. A split-muscle incision was made, and free turbid fluid encountered. Although the incision was enlarged only small intestines were seen and no trace of the large bowel could be found, but the duodenum merged into the jejunum uncovered by the colon. Suspecting an anomaly, another incision was made close to the midline and the cecum with an acute gangrenous appendix was found lying in the left iliac fossa with the tip of the appendix lying over the left pelvic brim. The appendix was removed with considerable difficulty and the patient recovered after a rather stormy convalescence, during which temporary enterostomy was required. A radiogram taken some time after operation (Fig. 1) shows the cecum in the left pelvis and the whole large intestine to the left of the median line.

Case II.—(47105), G. A., male, aged forty-two years. Consultation December 20, 1910. There had been no marked bowel symptoms. A diagnosis of gastric ulcer was made, based on a definite history extending over some twelve years. Operation December 29, 1910. A general exploration disclosed a chronically inflamed appendix lying in the left pelvis with the cecum and ascending colon on the left side. The appendix was removed. An ulcer was found on the lesser curvature of the stomach which had perforated to the pancreas, and a partial resection of the stomach was necessary to remove it. Gallstones were also present, for which a simple cholecystotomy was done. Microscopic examination showed early carcinoma of the stomach. The patient made an uneventful recovery. No radiographs were obtained in this case.

Case III.—(55210), W. G., male, aged twenty-four years. Consultation June 28, 1911. Referred by his home physician for recurring appendicitis. The history obtained from this patient was definite, and during an attack his physician had elicited the point of tenderness in the right iliac fossa extending over the pelvis. Operation October 4, 1911. The usual McBurney incision was made, but diligent search failed to reveal either the appendix or any part of the large bowel. This and the fact that the duodenum was not covered by peritoneum suggested a nonrotation. A low midline incision was made and the cecum and appendix were found in the left iliac fossa. The appendix was subacutely inflamed and was removed. Recovery uneventful. Radiograph (Fig. 2) taken after the patient left the hospital shows position of the cecum and ascending colon in the left abdomen.

Case IV.—(59276). E. C. W., male, aged sixty-two years. Consultation September 25, 1911. A history was given of long-standing abdominal cramps, without definite location, and associated with jaundice of a varying degree. Exploratory operation October 4, 1911. A thick-walled gall bladder buried in adhesions was found. Pancreas showed a moderate hardening. The condition apparently being due to a recurring cholecystitis, the gall bladder was drained. In the course of exploration it was noted that no colon was apparent in the right upper abdomen, the duodenum being uncovered by the colon and having no mesentery. Seach was made for the cecum and it was found in the left iliac fossa. Radiographs taken after the patient left the hospital (Fig. 3) represented conditions as noted above.

Case V.—(60378), J. L., female, aged sixty-two years. Consultation October 21, 1911. Patient gave a history extending over some years of attacks of cramps of short duration in the epigastrium, with jaundice, fever, and chills. Following these attacks there was a local tenderness in the epigastrium for two to four days. The symptoms were inconstant; they were not suggestive of any definite upper abdominal lesion, and the possibility of some reflex disturbance was considered.

FIG. 5.

Fig. 6.

Fig. 7.

Fig. 8.

Fig. 9.

During routine examination a distinct point of tenderness was found in the left lower abdomen corresponding to McBurney's point of the right side. The patient had a uterine fibroid of which she was made aware, and a laporotomy was advised. All over the left abdomen a high degree of tympany

Fig. 1.—X-ray, No. 13694. Plate No. 6 of bismuth series. Condition 24 hours after bismuth breakfast. Note shadow of entire colon coiled in left lower abdomen and pelvis. A single loop projecting an inch to the right border of the spine. Condition found previously at operation.

was elicited, and some anomalous condition was suspected; possibly an appendix lying in the left pelvis. A series of radiographs were made after a meal of bismuth (Figs. 4-9), and the whole extent of the colon was found lying in the left of the abdomen. Operation October 31, 1911. A median incision was made and the stomach and gall bladder were found normal. The duodenum, as in the other cases, was uncovered by peritoneum. The cecum and the ascending and transverse colon were found in the left abdomen; a condition practically identical with that in the foregoing cases. The appendix was adherent, contained fecoliths, and was removed. A pedunculated fibroid, attached to the fundus of the uterus, was removed by myomectomy. The patient made a satisfactory recovery

EXPLANATION OF PLATE.

Fig. 6.—X-ray No. 13650. Plate No. 3, bismuth series. Radiographed four hours after breakfast. Upper arrow indicates duodenum, arrow below shows tract of bismuth in stomach. Note two upper arrows on left side pointing to the two flexures. Gas in splenic flexure, bismuth in hepatic flexure. Lowest arrow on left indicates cecum; above it note position of iliocecal juncture, indicated by arrow. Contrast with plates, 4, 5 and 6.

Fig. 7.—X-ray No. 13650. Plate No. 4, bismuth series. Radiographed seven hours after breakfast. Single arrow on right indicates trace of bismuth in duodenum. Stomach and most of small gut empty. Terminal portion small intestine indicated by arrows. Upper two arrows on left indicate flexures of colon. Entire colon coiled up in the left iliolumbar region.

Fig. 8.—X-ray No. 13650. Plate No. 5, bismuth series. Radiographed ten hours after breakfast. Note tract of bismuth in small intestine. Entire colon coiled in left iliolumbar region. Arrows point out the two flexures of the colon. Contrast with Plate No. 6.

Fig. 9.—X-ray No. 13650. Plate No. 6, bismuth series. Radiographed 24 hours after breakfast. The colon has straightened itself out since Plate No. 5 was radiographed. Note absence of usual curves of sigmoid. Arrows indicate position of the two flexures. In this case colon is more strongly to the right of the spine than in either of the other cases demonstrated. Condition confirmed at operation.

THE NEW YORK QUARANTINE,

AND ITS ADMINISTRATION UNDER DR. ALVAH H. DOTY.

By T. MITCHELL PRUDDEN, M.D.,

NEW YORK.

In the old days when wind and fog, thunder and lightning, and errant stars inspired epidemics of disease, it was not easy to prevent them. But stricken individuals and their associates, as sources of contagion, were simply shut up or shut out or shut in, away from well and uncontaminate folks, and so disposed of. Anybody in those days who had force enough at his command could be an effective quarantine officer. Knowledge and discretion were not greatly in demand, in such a function, and the experience of a bailiff was as good as any.

But with the shelving of superstitions and the passing of the notion that disease is a thing to be personified, not a process to be controlled; and with the identity of many disease-inspiring microbes definitely known, the requirements of a modern quarantine officer have become many and exacting.

It will not do to-day at marine quarantines to force the great ships to swing at anchor under the yellow flag, with their panic-stricken passengers and their valuable cargoes, until suspicion dies out or a dread disease abates. Every hour counts in the lives of harassed and busy folks who may be detained, and in the large investments which commerce has upon the sea.

Among the hundreds, even thousands, of clean folks and dirty folks upon the ship, the Health Officer or his representatives must detect with precision the existence of communicable maladies, and in these later days, must put his finger on the "carriers" of sinister microbes, even though these same "carriers" be very pictures of health. He must know what to do and do it instantly, in the serious emergencies which often beset his path.

This modern quarantine officer of a great port like New York must know how to care for detained passengers of all classes with the least annoyance and discomfort which the facilities placed at his disposal by the State will permit. He must not only know how to discover but also how to treat infectious disease. He must command the resources of modern bacteriology and of modern disinfection and sanitation in all their phases. He must be in immediate possession of every fresh clue in diagnosis and every latest practical suggestion in the prevention and treatment of infectious diseases which the busy workers at the bedside and in the laboratories, the world over, are daily bringing to the service of threatened and suffering mankind.

He must have intimate knowledge, day by day, of the origin and course of communicable disease in all parts of the world, must be a keen judge of the bearing of these upon a possible or probable invasion of our ports through immigrants. He will be in close touch with the Federal and other officers at the ports of embarkation who nowadays form one of the strongest bulwarks against disease invasion, through the sanitary control of immigrants and their effects.

The local health officer will work hand in hand with the administration of Federal quarantine and must in person and achievement be respected and trusted by its representatives if the two systems are to work smoothly and effectively together.

The ideal quarantine officer will be informed and determined enough to follow the dictates of modern science, but wise and humane enough to do this with the least possible interference with the comfort of passengers and the interests [illegible]

whatever may have been true in the past, an enlightened public will not now permit without effective protest.

The recent action of Governor Dix in displacing from his charge Dr. Alvah H. Doty, Health Offi-

Fig. 1.—Swinburne Island.

And experience counts heavily in the successful administration of a great service like this.

A man then of special knowledge in many fields, a man of tried ability in the diagnosis and treatment of infectious diseases, an expert in sanitation and disinfection, a man of experience, wide observation, keen perception, good judgment, wise and forceful in emergencies and withal one devoted first and always to his chosen task; such is the man who can most successfully render the service to the public health which is demanded in the great modern quarantine establishment.

Any respectable doctor will not do to-day. There is no room here for politics. Political considerations or the liquidation of personal obligations by the appointing power should stamp the man or men who exercise or permit them, as traitors to a high trust and contemptible enemies of their fellow men. To appoint to such an office as this any other than the most capable and especially fitted man who can be secured, is to juggle with the health and lives of the citizens not only of a great commonwealth, but of a great nation, and to commit an offence which,

cer of the Port of New York, in view of the distinguished service which for sixteen years Dr. Doty has rendered to the people of the States of New York and New Jersey and of the United States at large, is most discouraging to those who have the interests of the public health at heart.

The importance of the quarantine at the Port of New York and the practical bearing which its wise and successful administration has upon the control of communicable disease, not only in this city but all over the country wherever immigrants go, renders pertinent at this time a review of some facts concerning the station and service here under Dr. Doty's administration.

Entering the harbor of New York from the sea as one approaches the "narrows" with Staten Island on his left, he passes two small islands, also on his left, and about a mile apart, which are built upon a shallow sand-flat scantily covered by water at the lowest tide. The outer, smaller island (Fig. 1),

Fig. 2.—Hoffman Island.

with its group of low buildings, is Swinburne Island, where are the infectious disease hospitals of the New York State Quarantine Service. The larger, Hoffman Island (Fig. 2), has an area of a few acres, and upon it are seen two large red buildings

*The illustrations in this article are published by permission from photographs copyrighted by E. A. Vusten.

with some smaller structures near by and grouped apart. These are the detention buildings of the Quarantine Service.

About three miles farther up, past the forts, which on either side guard the entrance to the upper bay, on the Staten Island shore, is the boarding station of the service (Fig. 3), consisting of the offices, laboratories, and the residence of the Health Officer of the Port, and his deputies; while at the pier in front of these lie the boarding, disinfecting, and other boats of the department.

Although the shores of New Jersey form the western borders of what we call the harbor of New York, and thus this State might legitimately share in the expense and the responsibility of the quarantine station at this port, New Jersey has continued to relinquish the privilege to watch and

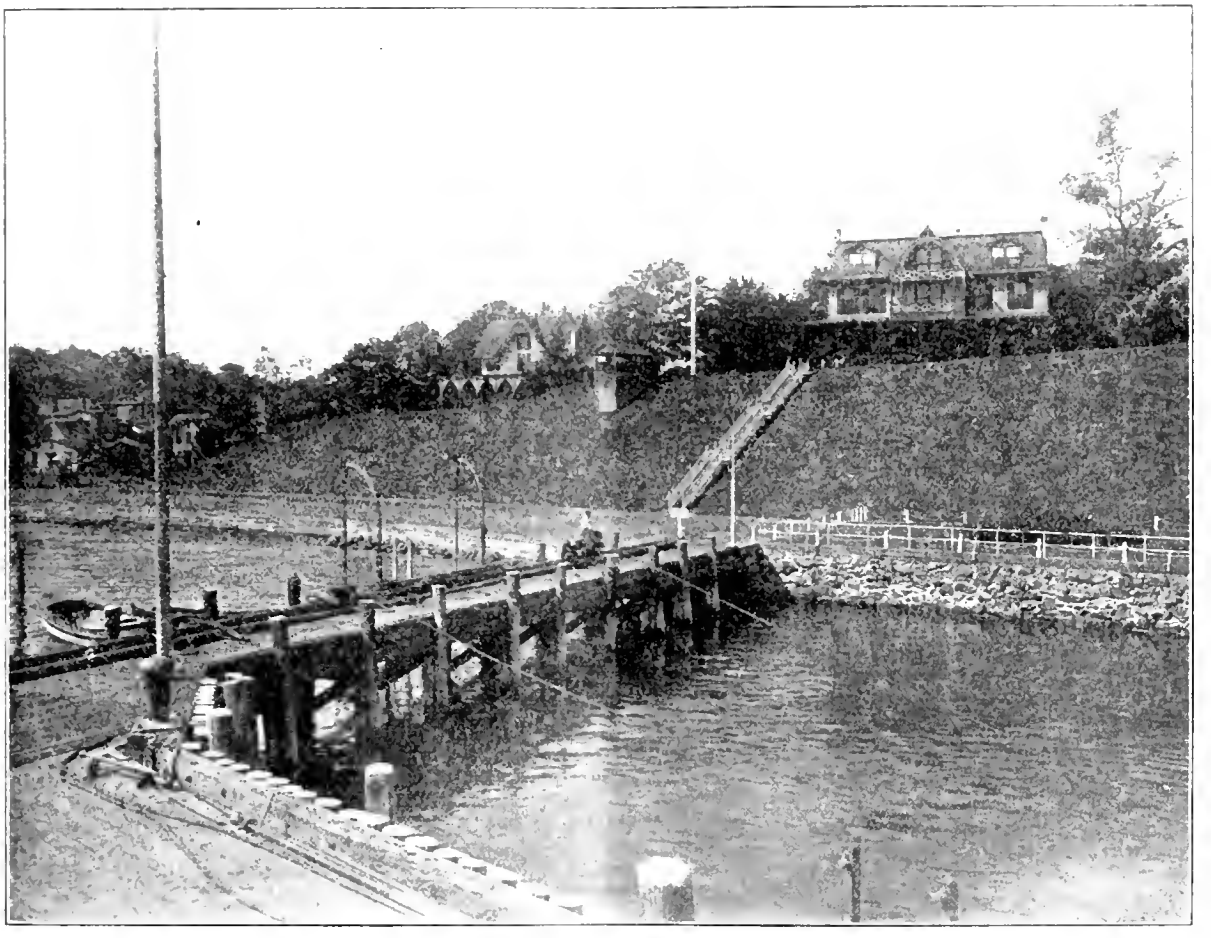

Fig. 3.—View of the Boarding Station of the New York Quarantine, looking shoreward from the wharf.

pay, and does not share in the councils of the quarantine, feeling no doubt that her interests are safe in the hands of her big neighbor.

The quarantine service at the Port of New York, the largest and in many respects the most important in the world, deals annually with immigrants often approaching and sometimes exceeding one million in number, who come in part from the very breeding places of pestilence in the far East, Africa, and South America. Some 6,000 ships are often annually inspected, some minutely, some not in the suspicious class, requiring only a formal assurance of freedom from disease aboard.

The enormous passenger traffic and the vast commercial enterprises centering at this port make it imperative that the business of the quarantine shall be conducted, as it may to-day, within the limits of safety, but with such dispatch as to form no serious bar to any of the interests involved.

Dr. Doty brought to the quarantine service, when he was called by Governor Morton in 1895, a large experience in the detection and control of contagious diseases won in a service of over fifteen years as Assistant Sanitary Inspector, Medical Inspector, and as Chief of the Bureau of Infectious Diseases in the Health Department of the City of New York. His noteworthy skill in diagnosis and his successful conduct of the important bureau in his charge had secured for him a high standing in the Department and the personal esteem of the Health Board, of which he became *ex-officio* a member on his assumption of the duties of Health Officer of the Port of New York. So closely linked are the functions of the Health Officer of this port and the Health Department of the city that the intimate knowledge of the methods of the latter which Dr. Doty brought to his new service became at once, and have remained to this day, an important factor in the harmonious cooperation of these two services devoted to the maintenance of the public health.

When Dr. Doty assumed control of the quarantine service the material plant was under the jurisdiction of the Quarantine Commissioners—a body of laymen, the motives for whose selection was best known in the councils of the dominant political party. Only the medical administration of these islands was in charge of the Health Officer until 1909, when the Quarantine Commission was abolished by the Legislature and the Health Officer placed in entire control.

Dr. Doty found the buildings on Swinburne Isl-

and old and dilapidated and the facilities for proper administration poor and inadequate. The condition of Hoffman Island, though considerably improved for purposes of detention under the spur of threatened and actual invasion of Asiatic cholera in 1892, was still most unsatisfactory in many ways.

Until October, 1910, the Department of Quarantine was maintained by fees collected from incoming vessels which, although commerce had enormously increased, gave a gradually dwindling income owing to the displacement of many small vessels by fewer larger ones.

The expenses, however, involved in the more accurate and costly procedures in scientific administration, in the increased number of attendants, and in the improved methods of disinfection and care of detained persons have necessarily increased. Fifteen years ago some two score persons were employed, now over one hundred are required, many of them highly trained for this special service.

After persistent urgency of the change by Dr. Doty the system was finally, in 1910, brought more nearly into conformity to that in other departments of the State, appropriations for maintenance being made by the Legislature and the fees collected at quarantine transmitted to the State Comptroller. Thus it is only for about a year that the quarantine service at this great port has had a regular income upon which it could depend for its maintenance and development.

In fact, Dr. Doty's administration throughout has been a constant struggle to maintain with efficiency, under inadequate appropriations the steadily rising scientific standards, to cope with such emergencies as now and then arose, and to rehabilitate a plant which, at the commencement of his service, was unfitted to the requirements of the station, the buildings dilapidated and the administration in many ways ineffective and out of date.

But the one thing which in all these years has been inflexibly insisted upon has been the efficiency, at whatever cost, of the scientific service involved in the detection and prevention of disease. That primarily is what the service is for. No doubt, under this stress the material conditions of detention which the State has afforded to those held for observation or treatment have been less attractive than could be desired, but have not, it is believed by those who know, been less salubrious than the conditions demand.

In order that he might gain a more intimate knowledge of the problems which he had to solve, Dr. Doty has in certain lulls in the service here visited the regions in which the ravages of plague and cholera are most persistent and threatening and the places from which merchandise, suspected to be a frequent source of infective germs, is constantly shipped. As a result of these personal observations, he has been able safely to make large concessions to the interests of commerce and to

Fig. 4.—Interior of the Hospital Ward, Hoffman Island

formulate with much greater precision than was formerly possible the measures of safety which the service requires.

No one in this country has done so much as has Dr. Doty to show by precept and by practice how many of the tedious and costly disinfecting processes of an earlier day were futile and unnecessary; to demonstrate how the agencies through which infective microbes are conveyed from one to another in disease outbreaks of obscure origin are seldom to be sought in the clothing and effects of well persons or in goods like rags and rugs, etc.—however dirty—but rather in incipient or mild or convalescent cases or in the newly unearthed "carriers." The establishment of these simple facts in marine as in other phases of sanitation has meant the saving of an enormous amount of futile labor. It has made possible the free movements of commerce where formerly there was endless delay and loss. It has let the passengers go free. It has largely contributed to the precision with which obscure outbreaks of communicable disease can be accounted for because it has drawn

attention away from the fictitious and centered it upon the real sources of infective stuff.

For many years Dr. Doty has maintained the service at this port in close and friendly relationship with the Federal quarantine of the Marine Hospital Service of the United States. The late Dr. Walter Wyman, Surgeon-General of the Public Health and Marine-Hospital Service, was at all times thoroughly familiar with the details of the New York Quarantine and was in cordial sympathy with the new measures which in the later years Dr. Doty instituted in the safeguarding of the port. It may be permitted now to state in this connection that only a short time before his death Surgeon-General Wyman, departing from a life-long reserve in this respect, wrote, unsolicited, a personal letter to Governor Dix in which he set forth the importance of the quarantine service here, his cordial approval of Dr. Doty's administration of it, and his earnest hope that in the interests of the public health he would be retained in his position.

Early in his service Dr. Doty requested the cooperation of a group of physicians of New York City with whom, as an Advisory Board, he might confer on various matters of policy and from whose experience in many practical phases of medical and allied sciences he might hope to profit in the service of the State. Very frequently throughout the season one or another member of the Advisory Board was called in conference in matters in which his special training might be helpful. Once yearly the board in a body visited the quarantine station to inspect the reconstruction of the plant and the new methods for increased efficiency.

From the beginning to the end of Dr. Doty's incumbency all political considerations have been excluded in appointments as in all phases of administration.

It is not necessary for the purposes of this paper to recount in detail the measures which Dr. Doty has himself taken, or in the earlier days of his administration secured through the cooperation of the Commission, to improve the quarantine plant and to bring the entire service to a higher state of efficiency.

While never throughout his incumbency have there been adequate general and specific appropriations for the improvement and maintenance of the quarantine plant and service at this port still step by step, year by year, both material facilities and methods of administration have been improved.

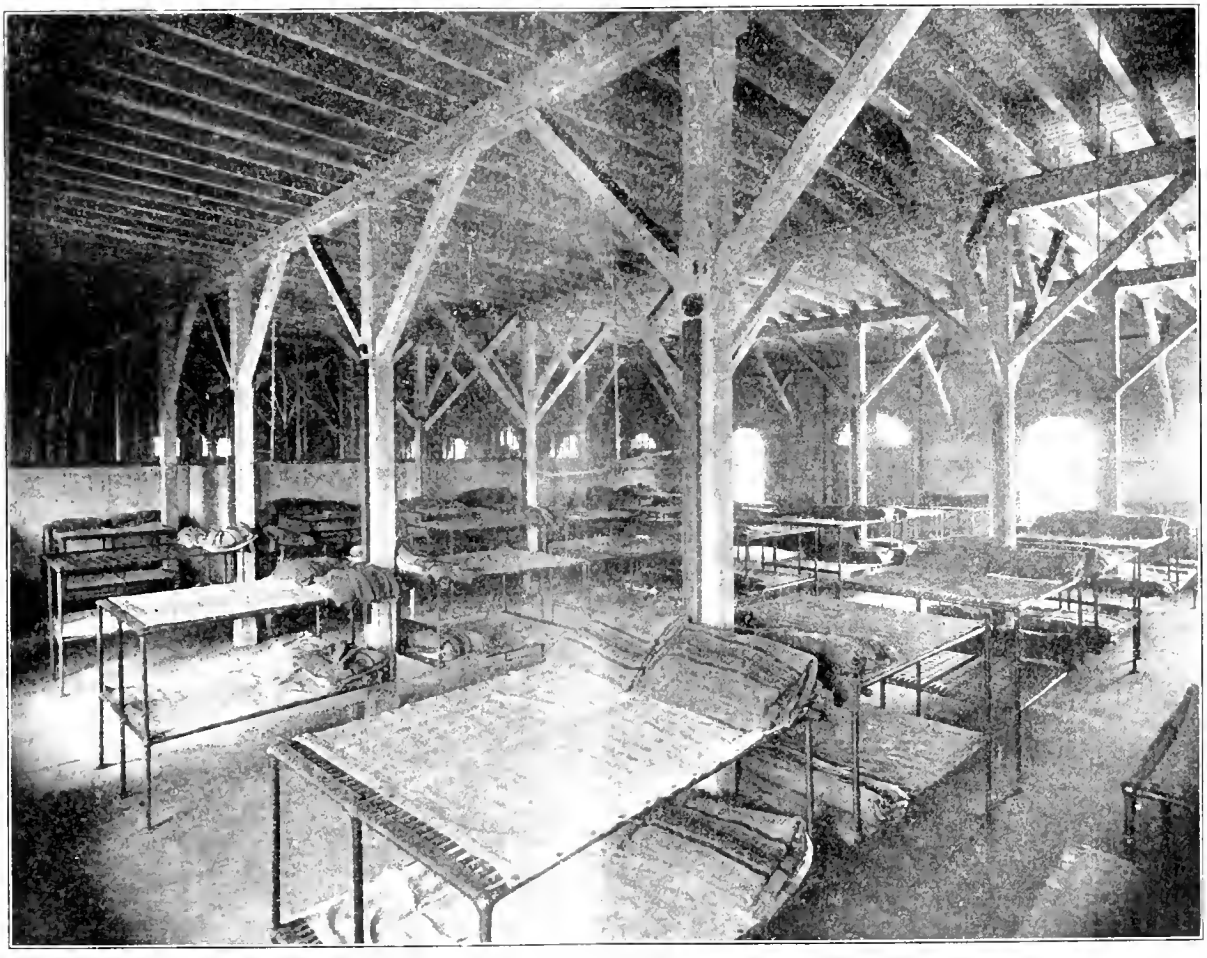

Fig. 5—Dormitory for immigrants detained for observation on Hoffman Island.

The ancient and dilapidated shacks on Swinburne Island have mostly disappeared, replaced by simple but adequate brick and concrete buildings properly constructed for the purposes of an infectious disease hospital accommodating nearly one hundred patients and administered by capable physicians and specially trained nurses. The water supply has been made safe by the installment of a new distilling plant for sea water giving some 4,000 gallons daily, and appliances for the destruction of infectious material have been provided.

Hoffman Island, during Dr. Doty's administration, has also lost many of its mediaeval characters. The enlargement of the island by a new sea wall, already begun in 1905, has been completed, the water supply has been rendered safe and more nearly adequate. The old detention buildings have

been renovated and refurnished. One of them has been reconstructed and new pavilions built for the purpose of a hospital for lesser infective maladies, such as scarlatina, measles, etc. (Fig. 4). Over 200 such patients may be cared for in the old and new buildings.

The sanitation system on Hoffman Island has been overhauled and provision made for the feeding and general care of from 1,400 to 1,500 persons detained for observation in emergencies (Fig. 5). On this island is the capacious disinfecting system installed under Dr. Doty's direction (Fig. 6).

At the lower end of the island is a cluster of new buildings carefully planned for the detention, with as little annoyance and as much of accustomed comfort as may be, of cabin passengers who may now and then be held for observation, or to complete a required period of incubation. Some of the buildings being not constantly required for passengers are used for nurses' quarters and for women and children of detained groups.

Thus it is that so far as could be done with the limited facilities at command the detention and hospital islands of the New York quarantine have been made over so as to meet as fully and effectively as may be the exigencies of this great public health service.

At the boarding station on Staten Island not less significant improvements have been made under Dr. Doty's administration.

In the first place the laboratories devoted to routine diagnosis and to research on special problems related to the service, mark the noteworthy advance within the past few years in knowledge of the infective diseases and the accuracy and minuteness of observation now often required in their detection. At the commencement of Dr. Doty's administration the service of one bacteriologist sufficed for the needs of the time. Now in emergencies from eight to ten trained men with their necessary attendants are kept busy with the routine of bacterial diagnosis. Many valuable studies have been made in these laboratories on the efficiency of special disinfectants and disinfecting processes, the exact value of which it is important to know in a service like this, in which the quick, effective, absolutely dependable destruction of infective microbes, under a great variety of conditions, is of extreme importance for the suppression and prevention of communicable disease, for the speedy releasing of detained passengers, and for the unhindered movement of merchandise.

Beside the wharf at the boarding station on Staten Island (Fig. 7) the tugs lie which convey the inspectors to incoming ships. Here also is the disinfecting steamer *Wadsworth* with steam always up, ready to go alongside a vessel, big or little, which may require its services or to move down to Swinburne or to Hoffman Island in an emergency. This disinfecting steamer is a unique instrument of protection against infectious diseases in the quarantines of the world.

The *Wadsworth* is a small steamer reconstructed for its special purpose. Here lying alongside any vessel or at a pier large numbers of persons can receive a cleansing shower while their clothing is passed through a chamber for steam disinfection, being ready and dried for them soon after their emergence from the bath. The *Wadsworth* has in practice proved to be a most important instrument in the efficiency of the service and in hastening the release of detained vessels.

The destruction of infective stuff in a great ship which has harbored some communicable disease among its passengers has always seemed a formidable undertaking. Whether it be so or not depends a good deal upon whether the man who directs the job has knowledge and common sense. Of the two perhaps the latter is the more important.

In the old days the people used to think of disease as something which existed by itself, which could attack a man or enter into him and slay him, or could lurk about in his neighborhood. So when a ship came into port with cholera, for example, on board, the quarantine officer didn't know whether the dreaded disease was confined to its victims or was dodging about among the bales of rags or boxes of merchandise or coffee sacks, and thus he felt that he must do something to the whole ship, though there was actually no reason for thinking that any other part than the immediate vicinity of the cholera victims was in any way contaminated.

What this officer actually did depended upon his epoch. Sometimes, long ago, he shut up the passengers for an indefinite time, they did well if they got off within the 40 days which give us the word quarantine—and then he burned both ship and cargo and the state paid the bills. Later a painful washing out of the vessel was gone through, or a little steam was introduced into its compartments, which at once condensing on the cold walls gave a moist, warm bath to microbes which might be lurking there, but was not at all inimical to their welfare. Or some more or less futile gas or fumes were turned loose in the ship's interior.

Long after the notion had been given up that the occurrence of one or more cases of contagious disease in one part of a ship, rendered the rest a source of danger, disinfection of ships at quarantine was maintained as a fetich, or later still as a bit of solemn mummery through which the health officer's fees could be collected.

The writer has during an earlier quarantine administration at this port, now mostly forgotten, seen the disinfection of an ocean liner, swaying at anchor in the lower bay, by the burning of a pan of sulphur on the open upper deck forward. When asked why the operation was conducted on the forward deck, the priest of this modern rite called attention, not without a tinge of superciliousness, to the fact that the wind was aft and hence the fumes did not incommode the sailors as would be the case if the ceremony were performed astern.

It took, in fact, a long time for quarantine officers, as it did others, to realize—and the conception is not yet quite domesticated in the general practice of sanitation—that the actual, potent risks of most infectious material in communicable diseases, center in the patient himself or in his excreta and in the direct contamination of persons or things in his vicinity.

When a ship comes into port to-day the attention is concentrated on the individuals who have been or are sick, and if the evidence of communicable maladies is clear the sick or suspected individuals or those who have come into intimate contact with them, their effects and their immediate surroundings in the ship, are the objects of concern to the health authorities of the port. But the ship's cargo, if the trouble has arisen in the steerage, the cabin passengers and all parts of the ship itself not subject to contamination may be safely disregarded. So ship disinfection in the quarantine routine is now usually confined to certain compart-

ments or certain rooms, to the effects of the sick persons or those of their associates and detention is limited to the stricken persons themselves or those who are thought for various definite reasons to require a period of observation to determine whether or not they may be harboring the suspected microbes and are or are not soon to manifest the symptoms of the disease.

Epidemics of communicable diseases to-day are usually concomitants of filth, insanitary living, polluted food or drink, and where none of these prevail are not to be expected and do not often occur. Hence it is that cabin passengers on the great ocean steamers are seldom seriously inconvenienced by the quarantine service.

The tasks and responsibilities of the quarantine health officer are greatly lightened to-day by the close scrutiny and cleansing processes to which

made ready for the quarantine inspector. Thus when the great ship slows down in the lower bay to meet the boarding health officer this functionary is able to cast a fairly accurate horoscope as to its immediate future as well as that of its immigrant passengers.

But it is just here that the skill, experience, judgment and resolution of the health officer are often most keenly tested.

Given some 700 to 1,000 variegated and polyglot immigrants lined up before a health officer on the deck of a slowly steaming or anchored liner, let us say without the story of any serious disease during the voyage, how is this official to decide, without delay, which, if any, of the motley group is likely to be or to become a menace to the folks ashore? The obviously ill afford no serious problem. Not a soul of those able to be about and

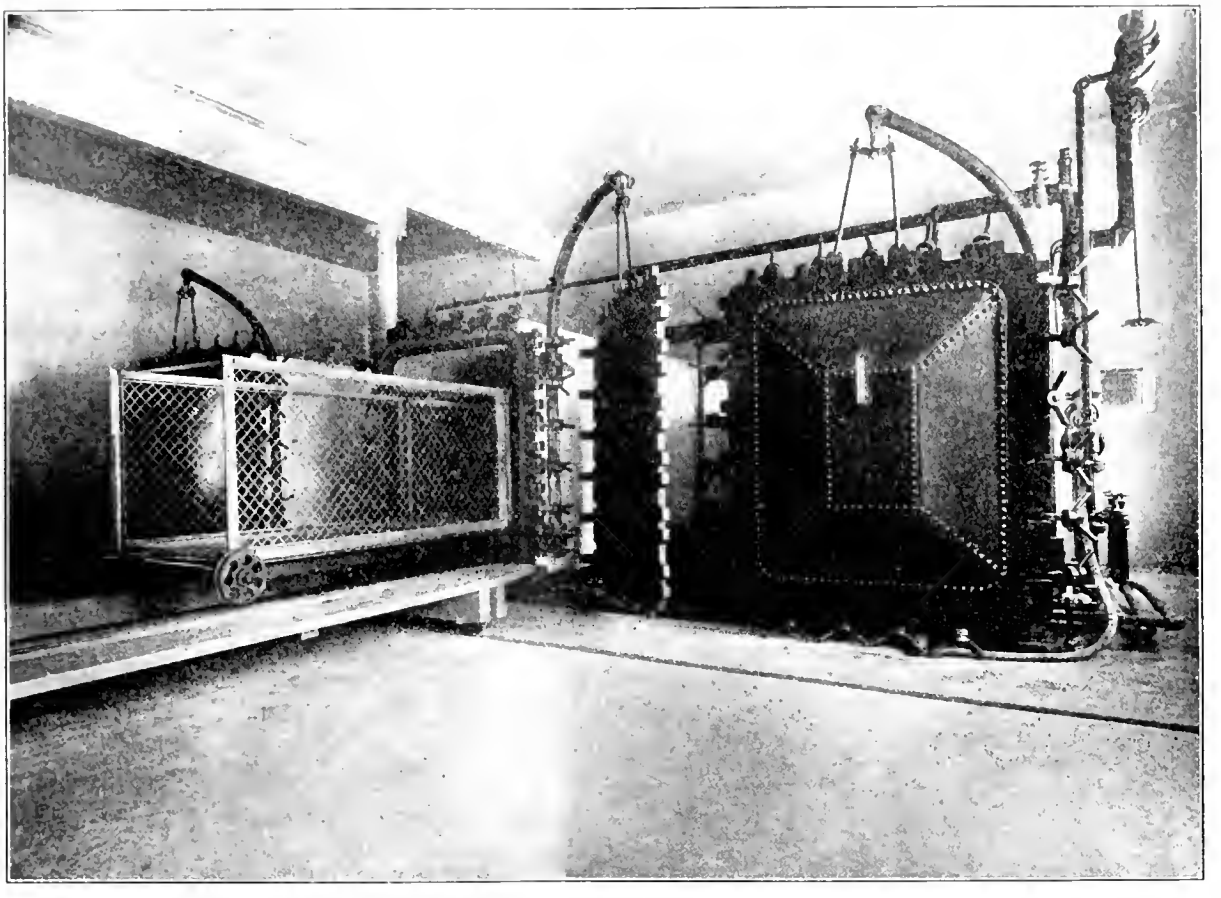

Fig. 6.—Disinfecting Chambers, Hoffman Island.

immigrants at many of the great ports of departure are subjected. Where such regulations are in force it will be known where every one of the thousands who storm the piers comes from, what conditions of health prevailed at his home before he left it. It will be known by the immigrant inspectors at these places how the epidemic tide, if such exist, is moving—up or down; what the type of disease is, mild or virulent. The would-be immigrant will be bathed and his effects disinfected should conditions indicate the urgency of these functions before ever he is permitted to set foot upon the ship.

Finally, the well-advised steamship company bearing immigrants to this port will see that the entire group is carefully watched en route and any suspicious illness wisely treated, or its victim safely isolated, if suspicion points to a communicable disease, and the complete health record of the trip

in the muster but will do his best to assume the jauntiness of health, although he feel it not. Some of them may be in the incipient stages of a serious disease which is not yet manifest either to its victim or to the most acute and trained observer. There are mild cases and there are convalescents from serious disease to be considered.

Then there are the latest additions to the responsibilities of sanitary experts—the "carriers" of microbes, who while not constantly, are always potential breeders of disease and now and then of epidemics.

Formerly, as the boarding officer passed down the lines of mustered passengers, each was forced to thrust out his tongue for inspection, under the ancient delusion that on this organ as on an open book could be read many dark secrets of our reticent interiors. But this unseemly performance

has been largely relegated to the junk shop of forgotten mummeries as a serious landmark of disease.

The passengers' own stories too were formerly considered as affording valuable evidence when the boarding officer could understand or believe them. But in these, under the conditions of haste, ignorance, bewilderment and the utmost temptation to deceive, the inspector has largely lost confidence.

There is one thing, however, which disease inducing microbes quite constantly do when once they settle down to the business of getting a living in the private bailiwick of their earth neighbor, man. They damage his delicate mechanism in many ways, and this damaged mechanism—almost sentient in its purposeful protective response to injury, releases chemical and other activities of the cells and organs from the close restraints of health, and fever follows—sometimes slight, sometimes intense. And here at last is something, this fever, whose recognition is precise because measurable. And the doctor drops the various hints of symptoms and roundabout makeshifts of observation with which he was formerly more or less content and reaches for the thermometer.

Under Dr. Doty's administration and at his suggestion a few years ago the clinical thermometer was introduced in the routine inspection of immigrants on shipboard in time of threatened yellow fever and plague. This practice is now largely followed in marine quarantine inspections at important ports. It was only after special studies instituted by Dr. Doty upon over 16,000 persons, under conditions prevailing among passengers and crews, that the data for estimating the exact significance of slight variations in the temperature were secured.

For, precise as they are, the stories of the thermometers as they come from the mouths of the inspected at quarantine must be wisely interpreted, since in many a sensitive person mild emotional disturbance or trivial ailments of various sorts may induce slight elevations of temperature which are passing and without noteworthy significance, as may be shown by a few hours under observation.

Of course, it is not at all times necessary to have recourse to the clinical thermometer. But when yellow fever and plague are prevalent in countries from which the immigrants come, it is of the greatest service. Even in such a time, if the ship doctor's record of the voyage be a clean one, after the few who may be judged to have a suspicious temperature are held for observation on Hoffman Island, often only over night or for a day, the remainder are at once allowed to go their ways.

When cholera, plague, or other serious communicable disease has actually occurred on the voyage the inspector has a more difficult decision to make. If the cases have been at once isolated and properly cared for, all that may be necessary is to remove the sick who at this port go to Swinburne Island and hold those with elevated temperatures at Hoffman Island for observation.

If, however, such cases have appeared en route without proper isolation and care, and if new cases are developing, it is commonly necessary to remove the sick to Swinburne, and the entire body of immigrants to Hoffman Island for observation, and for the disinfection of such of their effects as may require it, and to cleanse the compartments of the ship in which illness has occurred or those which could have been contaminated.

With the careful inspection and disinfection at ports of embarkation which is now common and with the immediate isolation and care of those cases of plague, cholera, etc., which may develop during the voyage, so vital for the interests of the steamship companies, and the systematic use of the clinical thermometer, it is not nowadays often necessary to hold an entire shipload of immigrants for observation. When this is done a close watch is kept upon them all for the first possible manifestation of disease which is followed by transfer to Swinburne Island. Thus it is usually found practicable after a few days to discharge the group after such disinfection as may be required. Smallpox is readily controlled, as a rule, by vaccination, but requires unremitting alertness on the part of the health officials.

By the judicious use of all these methods of the modern marine quarantine, it has been possible for Dr. Doty at the port of New York to protect the people of the country from such infective maladies as have from time to time threatened, and this with but a trifling interference with private or commercial interests. This is a great achievement in view of the large number of vessels annually entering the port and the immigrants of all classes swarming hither from all sorts of pestilence-breeding localities. It has required ceaseless vigilance and a wide knowledge of the steady advances which science has made year by year.

Few realize, though modern methods have done much to lighten the burden of his task, the harassing responsibility which rests upon the health officer in releasing from quarantine a ship load of immigrants among whom have appeared cholera or plague with all their sinister possibilities.

The modern quarantine officer, with all his resources, cannot insure the country that no case of communicable disease shall ever pass the barriers. His aim is to take those precautions which, all things considered, are required and justifiable for the common good. And the development of modern science has shown that this may be done without serious damage to anyone, either in person or pocket.

This larger view of the quarantine requirements, which tempers the claims of tradition and the theoretical exactions of science necessary in the laboratory, with the lessons which world-wide experience has taught, for many years, and far in advance of most countries, has mitigated the rigors of quarantine at English ports and at the same time secured for that country practical immunity from imported epidemic maladies.

The necessity for, and the possibility of safely achieving, this comprehensive aim of modern quarantine has been persistently urged by Dr. Doty in many noteworthy papers prepared for the medical profession at large, and for special officers of marine sanitation in this and other countries, among whom he holds a place of influence and high honor.

The problem of "carriers" is one of the most perplexing of those with which modern sanitation has to deal. It has long been known that after recovery from diphtheria, virulent bacilli might remain for various periods in the throat or mouth and render the secretions of these capable of inciting the disease in others, through unguarded spitting, coughing, and sneezing, through kissing, and in other ways. More recently the germ of typhoid fever has been shown sometimes to persist in the excreta long—even years—after con-

valescence. In this way serious outbreaks of typhoid fever have been traced to carriers who were dealers in milk and in various ways concerned in the handling of food. Similarly in times of cholera, the digestive canal of persons in health may harbor germs fully capable of inciting the disease in others, if by any mischance they should find their way into the food of susceptible persons.

"Carriers," then, are persons in whose bodies infective microbes are not destroyed, but on the contrary may flourish for long periods without detriment to their own health, while setting free enormous numbers of germs highly virulent for others.

It is only by close personal contact of carriers with others, or by such uncleanly practices as lead to the contamination of food or drink that the damage occurs.

examination of the intestinal contents of every immigrant and members of the crew on board ships entering this port under suspicion of cholera contamination. In this way several cases have been detected which must otherwise have gone free as a persistent menace to others.

What is to be done with "carriers" of cholera and typhoid germs is too large a question to be profitably discussed here. They cannot be indefinitely sequestered—well folks as they are—even for the good of the community. Doubtless a fuller knowledge of the conditions under which such sinister germs can persist in healthy persons will bring useful counsel. Or, direct means will be discovered to relieve them of their incubus.

In the meantime, here, as in many other sanitary questions, the larger view is the wiser one, and common sense and experience are the best arbitors.

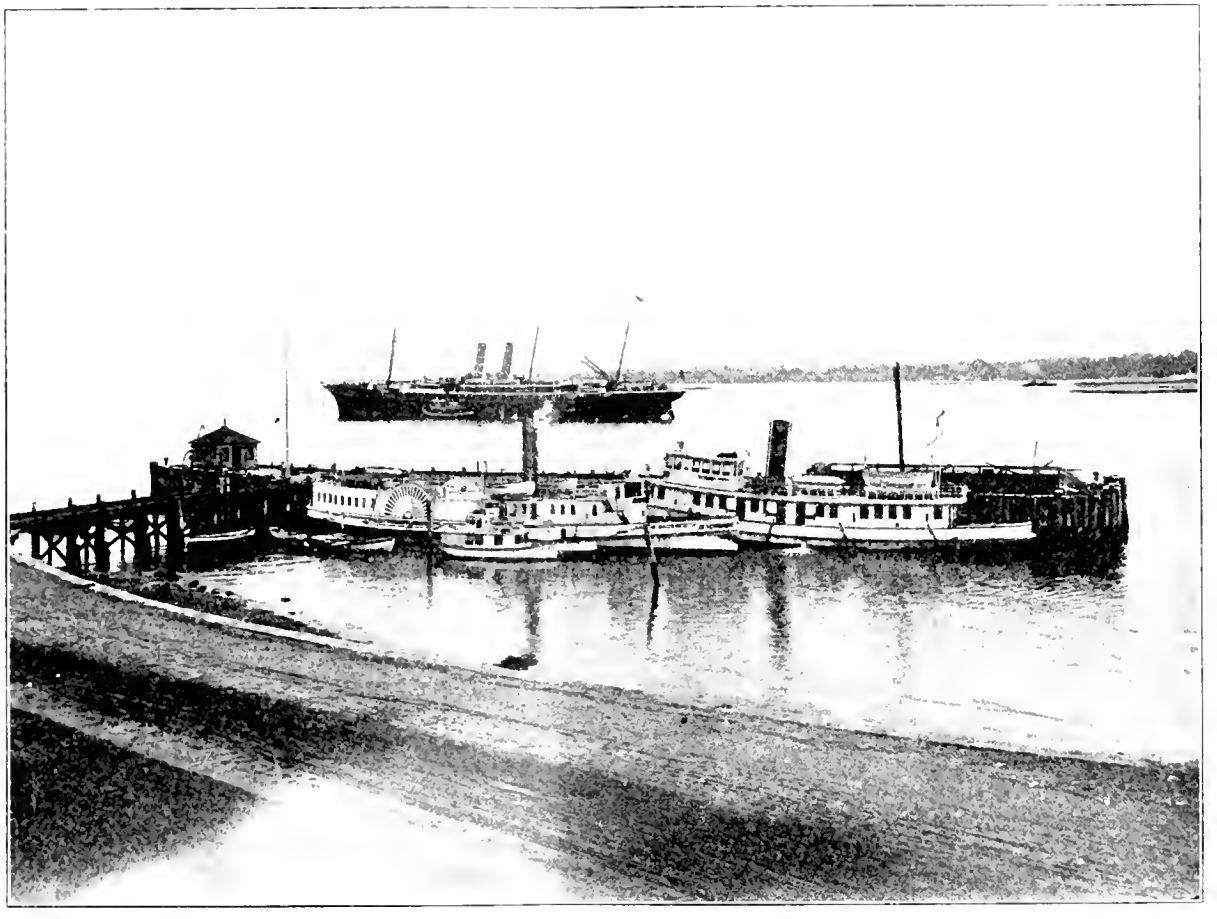

Fig. 7.—View of the wharf of the Quarantine Boarding Station, showing the department boats and a foreign vessel at anchor and under inspection by a quarantine officer.

But even carriers themselves are not always proof against infection. Let an even slight disturbance of the nice balance which we call health occur, and immediate invasion may take place with serious illness. Thus so slight a disturbance as that induced by a dose of a cathartic drug, normally, perhaps salubrious, may speedily convert a cholera carrier, harmful only to others, into a cholera victim.

How are carriers to be discovered, and what is to be done with them when they are found out? The importance of the detection of cholera carriers has only recently been emphasized by the discovery of several such persons at the New York Quarantine. Keenly alive to the significance of this discovery, Dr. Doty early last year assumed for his station the enormous burden of a bacterial

One cannot make every individual in a community germ free or germ proof, and nearly all health regulations which relate to the suppression of communicable diseases are more or less a compromise between what is ideally desirable and what is practicable, all things considered.

One of the most striking advances which science has made within the past two decades in the knowledge of quarantinable diseases is in yellow fever.

It was formerly believed that this serious epidemic disease was readily conveyed by the clothing and effects of its victims. The result was that when these were not destroyed they were subjected to disinfection, often at a great cost of time and labor. When ships came from ports at which yellow fever prevailed, these, too, it was thought must be disinfected; at least, the passengers were

objects of serious suspicion, and were often subjected to extreme annoyance and delay.

Early in Dr. Doty's administration he convinced himself from the various records of epidemics of yellow fever that there was no evidence of its spread through the clothing or effects of victims of the disease or of their associates. On this conviction he discontinued the disinfection of ships and goods from yellow fever ports, confining his attention to exposed and non-immune persons who were compelled to defer landing until the traditional five days' period of incubation should have elapsed.

When, finally, the agency of the mosquito in the conveyance of yellow fever was established, Dr. Doty's convictions and practice, which had been looked askance upon or had been the subject of active protest, were abundantly vindicated.

When Governor Dix assumed his office at the beginning of 1911, it was feared lest he might follow the tradition of some of his predecessors and regard the position of Health Officer of the Port of New York as political spoils, and as Dr. Doty's term then expired, replace him by a man of untried capacity, but of political affiliations with himself. He was early advised by many citizens familiar with administration of quarantine at this port, and with the long and distinguished service which Dr. Doty had rendered to his State, of the extreme importance of retaining so efficient an officer.

As the months passed, while it was disquieting to those who have the health and lives of our citizens at heart, that Dr. Doty was not reappointed, it was still hoped that the Governor might prove to be among those public-spirited officials who regard the welfare of the people which they are pledged to foster, as of greater importance than the clamor of office seekers or the claims of political allies.

In the autumn of 1910 Asiatic cholera assumed a threatening aspect in Europe, and the incoming ships, especially from Mediterranean ports, became the source of extreme concern to the Health Officer. But Dr. Doty had the quarantine system well in hand and with only the slightest interference either with passengers or commerce, the ships bearing infected passengers were safely cared for.

It was evident, however, that again in 1911 similar vigilance and care would be required in dealing with the tide of incomers from infected districts, and, in fact, the summer brought ship after ship with suspicious persons or actual cases of cholera on board.

While every effort was being made to prepare for the serious emergency thus expected, it was announced that Governor Dix had decided to investigate the quarantine service at this port, and Mr. Chas. N. Bulger, of Oswego, N. Y., was named Commissioner for this purpose.

The inquiry was instituted by Commissioner Bulger in New York in the early summer, and so far as fairness and propriety were concerned, soon developed into a dismal farce. The shabby treatment of witnesses not obviously testifying to the detriment of the quarantine administration; the eager elaboration of the gossip and petty complaints of a few discharged and discredited servants of the service; the solicitous fostering of the alleged grievances of a small collection of ignorant immigrants, all too easily lured to testify to any fancied hardship, was all that an assiduous exploitation of the underworld afforded in this preposterous inquisition.

Throughout the long rambling proceedings one consistent impression was always to the fore, namely, that at all hazards evidence must be secured to make Dr. Doty's removal seem justifiable or necessary.

Meanwhile, harassed as he was by the ill-timed and often preposterous demands made upon him or his associates by Commissioner Bulger, Dr. Doty stuck to his job—which just then seemed to center in keeping out of the country the infective agent of Asiatic cholera so seriously threatening, and requiring every thought and energy which the quarantine service could concentrate upon it, rather than following the antics of the exigent Commissioner and his shabby coadjutors.

The results of the inquiry were finally framed into a report to the Governor by his Commissioner, which is a masterpiece of misrepresentation, ignorance and malicious invective not often equaled in the annals of a modern state.

Dr. Doty's methods of accounting were criticized, but have been shown to be adequate, and at least all that could be expected from an officer upon whose shoulders had been suddenly thrown the business management of a great station at a time when threatened cholera invasion required his most earnest personal attention.

The quarantine at this port obviously needs and should have more liberal appropriations, provided the officer at its head is sufficiently informed in science and administration to know how wisely to expend it. There should, of course, be a professional accountant responsible alike to the Health Officer and to the Comptroller of the State.

The strictures of the remarkable sanitarian from Oswego upon the scientific conduct of the quarantine in general and of the treatment of certain ships and persons in particular, form a rather noteworthy composite of ignorance and spiteful irrelevancy. The Governor in a subsequent, violent letter to Dr. Doty, demanding his resignation, adopts the findings and the furies of his Commissioner.

The Governor is disposed to attribute to a beneficent Providence the salvation of the country from devastation due to the distribution from quarantine of cholera, which he alone, with his newly unearthed sanitary expert, has discovered. Might one respectfully suggest to his Excellency that the country will be saved from pestilence, according to a more modern view, rather by the vigilance and efficiency of local health officials who elsewhere are permitted to meet emergencies unembarrassed by ill-timed and preposterous inquisitions and scurrilous abuse from their superior officers of the State.

One by one every noteworthy charge against Dr. Doty's administration has been answered to the Governor, but these answers are all suppressed or ignored in the Governor's final letter to Dr. Doty asking for his resignation. Perhaps the only part of the Commissioner's report which deserves a moment's serious consideration is a collection of rather verbose criticisms of Dr. Doty's administration of the quarantine, in which it is attempted to show that his practice on certain occasions did not conform to the rules which he and others had somewhere laid down. To this one may say that, when all is ready at a modern quarantine station to detect disease, to clean clothing, material and ships, and to provide for sick and detained passengers, there yet remains one prerequisite to an ideal

administration, namely, the right man at the head. Sanitary science is not yet, if it ever will be, an exact science. There is always a large borderland in its administration in which good judgment, large experience and an open mind must be linked to expert knowledge if the best results are to be secured. Rules there are for quarantine service as for all phases of disease prevention. But the man who is really fitted to control such a service must be stronger and wiser than the rules, of keener insight than the devotee to formulas, and ready and willing to break or to transcend them both when the proper occasion comes.

It was the failure to recognize this factor in sanitary administration which made possible many of the callow criticisms of the Commissioner in his strident report to the Governor. Some of the very performances which seemed to this official critic to show inconsistency or unwisdom or neglect on the part of Dr. Doty were the precise things which revealed the trained sanitarian, the wise and forceful executive, and the devoted guardian of the public health.

The competent executive in sanitation must be prepared to make exceptions to all rules in some emergencies; to trample upon all traditions for the nonce: and only so—now and then, can he win a successful fight with irregular phases of disease invasion. The ignorant will be shocked, the wiseacres of tradition will wag their heads, and the malicious will revile, but the proof of the pudding is in the eating. Dr. Doty has kept threatening epidemic invasions well in hand at this port for sixteen years, some of them exceedingly strenuous ones, and though his methods appear to horrify the versatile Commissioner, and though the Governor in the plentitude of his wisdom and piety attributes our salvation to Providence, those who really know are apparently disposed to think that New York has had an uncommonly alert, experienced and successful health officer of the port.

Of course, neither Dr. Doty nor any other individual is indispensable to the conduct of even one of the world's affairs, and the New York Quarantine will continue to be administered some how.

The most disheartening feature in the situation created by Governor Dix is that we are forced to realize that at a time when the whole civilized world is turning its attention and its hope to disinterested service in the prevention of disease, not even an office like this, touching the personal welfare of so many citizens, should be free from the smutch of high official brigandage.

The health officers of the State of New Jersey will do well to take note of the risks to which Governor Dix is so jauntily exposing their charges as well as the citizens of his own and other states.

Federal quarantine officials have once felt obliged to establish for a time their own protective system outside that of New York State when they were convinced that the latter had become a menace, not a protection, to the public health. And they may well find themselves again compelled to assume a similar responsibility if this service is to be prostituted by the Governor to private or political exigencies.

Those who have cherished the hope that local self-interests might never again be permitted to interfere with the public health service, will inevitably turn to the possibilities of the permanent Federal administration of our New York Quarantine. This is, no doubt, what will ultimately take place. No suggestion of this has been made by Federal or other authorities within the past decade and a half because the administration of the service here has so universally inspired confidence.

If those, whose efforts have lately been so faithfully directed toward the establishment of a National Health Bureau or Department, could overcome the sinister influences which have thus far succeeded in thwarting their efforts, we might the more strongly and more immediately urge the establishment of a Federal quarantine at this port which should be part of the greater organization.

One does not believe that ever again in this or in other civilized communities plague and cholera and other such pests can ravage as they sometimes have, and do still, in the tropical and eastern hotbeds of disease, because the sanitary safeguards are too well known and too efficiently controlled.

Nevertheless, neither those who travel by sea nor those concerned with commerce can view without regret the unnecessary placing of the greatest quarantine service of the world in untried hands. Governor Dix has evidently made up his mind to be responsible for the few lives which would almost inevitably be sacrified through an ineffective quarantine service, and to take the risks of the larger loss in health and life and property should a not improbable more serious calamity befall. It is pertinent to ask, however, whether the people of the State of New York—to consider them alone whose officer the Governor is—are satisfied with the only too obvious motives which inspire this political juggling with their welfare.

One would like to think that Governor Dix has been deceived, that he has acted in haste, overlooking somewhat the significance of his performance, in the press of many urgent duties and engagements.

But through all his actions in the affair, recorded and unrecorded, one is forced, much against his will, to read the shabby drift of the whole matter—the displacement of a faithful officer of the State under cover of a mock investigation and a prodigious defamatory hullaballoo.

A CASE OF FULMINATING GENERAL PARESIS, WITH AUTOPSY.*

By ALEXANDER S. LEVERTY, M.D.,

NEW YORK.

PHYSICIAN TO THE NEUROLOGICAL CLINIC, INSTRUCTOR IN NEUROLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK, CLINICAL ASSISTANT IN THE DEPARTMENT OF NEUROPATHOLOGY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE case that I am about to report presents three interesting features: First, the extragenital seat of the initial lesion. Second, the rapid and furious course of the disease. Third, the report of the findings of the autopsy as the disease was in a relatively early stage.

Summary.—Male, age 45, finger infected in 1900, syphilitic monoplegia in 1909, cured. First symptoms of paresis January, 1911: death from paresis three months later. Autopsy, characteristic findings of paresis.

The patient was a man, American, 45 years of age, a hardware clerk without any known hereditary predisposition to insanity. The history of the grandparents on both sides is unknown. His father, however, died of phthisis at an early age. His mother died of cancer of the stomach at 60. Two

*Read before the New York Psychiatrical Society, January 3, 1912.

sisters and one brother are living. One sister had a severe attack of "nervous prostration" from which she recovered. One sister is sensitive, impulsive, and has had numerous attacks of emotional instability and general restlessness. One

of a [illegible] manipulation of the genitals of an infected [illegible].

At first he thought it was a runaround and treated it with [illegible] poultices and did not consult a physician until [illegible] secondary symptoms appeared. He was treated for eighteen months, after which time he discontinued treatment. Contrary to the advice of his physician he married one year after his infection. His first child died of meningitis at less than a year. The patient was of a nervous tempera-

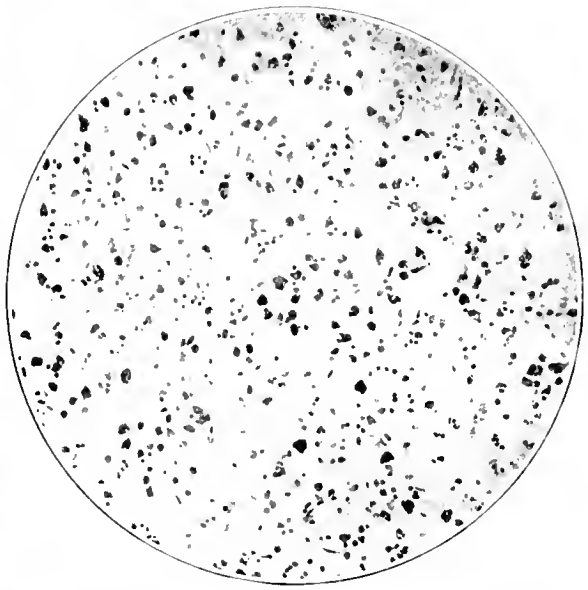

Fig. 3.—Right Paracental Cortex, X 190. (Toluidin Blue.) Same section as Fig. 2. Shows degeneration of pyramidal cells and infiltration with numerous lymphocytes.

ment. His habits had been industrious and at times he had worked very hard, but used no alcohol or tobacco in excess.

In 1906 he complained of being nervous and irritable, of pains in his head, and of inability to apply himself to his work. This condition lasted for a month, when he apparently got well. Three years later, in 1909, he was suddenly attacked with weakness and paralysis of the right arm. With strenuous antiluetic treatment he regained the use of his arm in five weeks. He remained well and attended to his business until the latter part of Jan-

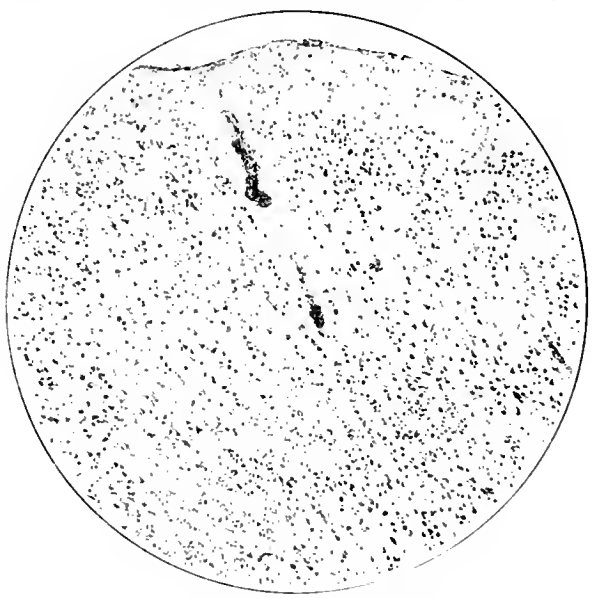

Fig. 4.—Right Temporal Cortex X 75. (Toluidin Blue.) Shows chronic meningitis, engorgement of blood vessels, and exudation of lymphocytes.

uary, 1911, when he began to express an exaggerated sense of well being, saying that he was to be taken into the firm for which he worked. On arriving home one afternoon, he displayed $200, which his employers had given him for the purpose of

taking a rest, as they had noticed a change in him, saying, "everything is all right now," and adding that when he returned to work he would be admitted to the firm. This state did not arouse the suspicions of his wife or relatives, and they did not suspect that

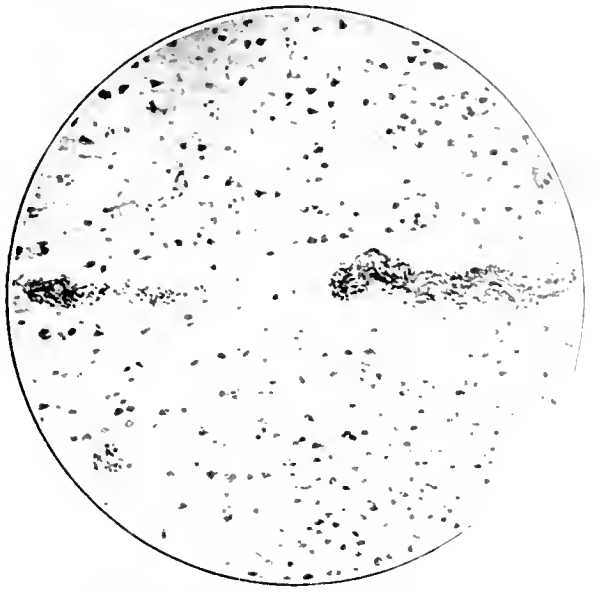

Fig. 5.—Right Temporal Cortex, from same section as Fig. 4, X 190. (Toluidin Blue.) Shows overgrowth of endothelial cells of capillaries, on the adventitial sheath of which are seen the characteristic plasma cells and many lymphocytes. There is marked degeneration of the cortical neurones.

he was mentally wrong, until he was examined.

The somatic symptoms were Argyll-Robertson pupils, tremors of the face, tongue, and hands, changes in the deep reflexes, defects of speech and of handwriting. Ten days later he became incoherent, maniacal, and furious and was sent to a sanatorium (February, 1911). The delirious mania continued until his death in April, 1911, less than four months after the onset.

The following is the report of the autopsy: Au-

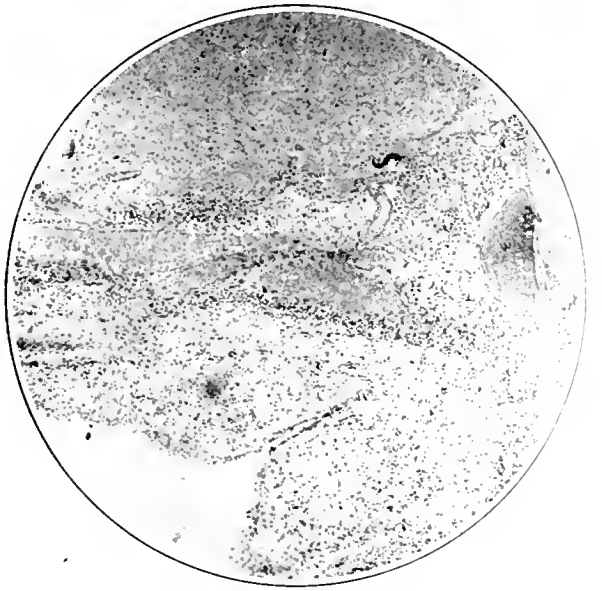

Fig. 6.—Right Frontal Cortex, X 75. (Toluidin Blue.) Shows chronic meningitis, congestion of blood vessels, with increase of cellular elements along vessel wall.

topsy was performed about three hours after death. Permission was given to examine only the head, and the body was not opened. The calvarium was somewhat thickened and the dura mater more than usually adherent to the bone over the top and front of the brain. There were no adhesions between the dura mater and the pia mater. There was nothing noteworthy in the appearance of the dura or of any of the dural sinuses. The base of the skull appeared quite normal.

The pia mater was slightly edematous especially over the frontal and vertical regions of the brain, and in these regions the pia mater was considerably thickened and appeared milky. This latter appearance terminated abruptly at the middle of the top of the brain, so that a fairly definite line could be seen, in front of which the pia was considerably thickened, while behind it the pia mater was but slightly altered. On the right hemisphere this line was at a plane about 1 in. behind that of the left hemisphere. As one palpated the brain as one would in detecting fluctuation, there was a definite decrease in resistance at this line, so that in front of it the resistance was marked as compared with that behind it.

The Pacchionian bodies were hypertrophied and increased in number. At the base of the brain the pia was slightly but not much thickened, and the

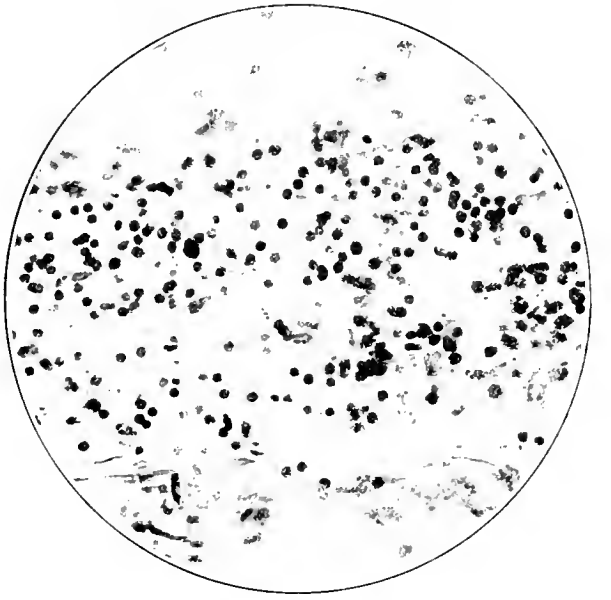

Fig. 7.—Right Frontal Cortex, same section as Fig. 6. X 250 (Toluidin Blue.) Shows exudate of lymphocytes, and felt work of plasma cells along adventitia.

vessels there looked to the naked eye delicate and normal.

The brain weighed 1,530 grams, a weight slightly above the average. The convolutions were well rounded, there was no focus of alternation detected anywhere.

Macroscopically the brain looked like a typical case of paresis, in which the disease, though it had spread to include the front half of the brain, had not yet caused much shrinkage.

Microscopically there was found a meningitis with characteristic cortical changes of the type belonging to paresis. (Fig. 1.) There was a productive inflammation of the pia mater. The meningeal changes consisted of intense engorgement of the blood-vessels, thickening of the vessel walls, exudate of lymphocytes, marked proliferation of cells in the adventitia and perivascular spaces with formation of the characteristic plasma cells. (Figs. 2 and 6.) The cortex showed proliferation of neuroglia. Many of the cells were degenerated. There was chromatolysis, with loss of central position of the nucleus, which in some cases had reached

the periphery of the cell. (Figs. 3, 5 and 7.) Mast cells and spindle cells were also present. The disease had not, even in the frontal regions, progressed very far; that is, comparing this case with many others, one can say that there the disease was in a relatively early stage. There is, however, absolutely no question as to the type of alteration found.

The autopsy was of special value, owing to the fact that the disease was in a relatively early stage, and in a case which clinically ran a rather quick and stormy course.

The cause of death, while undoubtedly intimately associated with the paretic brain process, cannot be asserted to be due immediately to it, as it appears clinically that the visceral functions were much impaired, and that toward the last these played a leading part in the termination. But just what should be ascribed to the various visceral organs it is impossible to say, as they were not examined post mortem.

707 St. Nicholas Ave.

OVERCROWDING AND DEFECTIVE HOUSING IN THE COUNTRY DISTRICTS.

By HARVEY B. BASHORE, M. D.,

WEST FAIRVIEW, PA.

COUNTY MEDICAL INSPECTOR, PENNSYLVANIA DEPARTMENT OF HEALTH.

It is hard to believe that overcrowding, a disease generally only prevalent in the great cities, is present in the country districts; yet to a close observer this will be apparent in many places. Although I had been conversant with the country all my life, I never realized that such conditions existed until I became connected with the State tuberculosis work. I little dreamed that we had situations in our villages and small towns just as bad as I had seen in the great East Side on Manhattan Island. Who would believe that rear tenements existed on a village lot—in a village of a thousand inhabitants, where land was almost as cheap as the proverbial "dirt?" Yet such does or did exist. Why not? Greed for gold is as strong in the country squire as in the city millionaire, and the owner of a few lots is going to make the most of them, whether in city or country.

Many of the workmen's houses in the small industrial villages of Pennsylvania are built in rows, so that only the end houses can have light and air on more than two sides, a condition which may become necessary in the crowded centers of population but which is not necessary in small towns. Once when I was driving through a little mountain valley in the backwoods of this State, I came across just such a settlement made up of the houses of the workmen of a nearby industry; rather, there were no houses, only one long row divided into compartments, called houses on the company's books; the conditions here were scarcely better than in a city block, and the inhabitants, pale, sallow, dirty and unkempt, living in badly ventilated rooms, showed the typical countenance of the overcrowded. Yet right here there was land in plenty, land everywhere, that nobody wanted—land for ten dollars an acre, and the people were suffering from overcrowding and defective housing because the company employing them was too penurious and too careless to build houses fit for human habitation. In another village I saw, and it still exists, a house built on the entire lot, so that the privy accommodations are actually on the street; in this case the condition was born of the greed of a bankrupt speculator.

Fig. 1.—A sample of bad housing in the country; plenty of fresh air outside, but sadly lacking on the inside.

In the case of the rear tenement [illegible] above, it is interesting to note that it has held several families, every one of which has included cases of tuberculosis, and the people in the locality are becoming so wrought up about its unhealthfulness that just at present nobody will move into it, and it is likely to be torn down before long. I am thinking of another house, or rather row of houses, which is a good illustration of the architecture so responsible for overcrowding in small towns. This row, supposed to be three houses, at one time contained seventeen people, and as there are only three bedrooms in the whole row, there was evidently a vast amount of overcrowding. The gable ends of the building show great lack of window space, presumably left in this condition with the intention of adding more "houses" to the row at some later date. Why are such houses, insanitary they surely are, built in our towns and villages? Simply because the owner hopes to make 10 or 15 per cent. on his investments; and many an opulent family lives on the proceeds of a "rotton row" that is a disgrace to modern sanitary knowledge. These people—the proprietors, I mean—generally the best people in their respective communities, fail to realize that insanitary dwellings, built perhaps in sunless rows on another street, are a menace to their own health. I just happen to recall the case of a small town in which the worst and most insanitary shack is owned by the wife of a college professor, and she herself also a prominent member of the local civic club.

Another phase of overcrowding in the country, just as in the city is the "lodger evil," especially in small towns on the "boom." I know of a certain small town, and a certain family—a typical case—in which this condition exists; the family of five adults are living in a six room house and take one boarder. They are frugal and industrious Americans and are trying to pay for their small home; and they are doing it, but at the high price of overcrowding; one daughter has died of tuberculous meningitis and another at present has the appearance of developing the pulmonary form of the dread disease. Overcrowding, too, is very often wholly due to the habits and ignorance of the people themselves, neither environment nor landlord being responsible in the least. For example, a nurse from one of our dispensaries, in her visiting work came across a certain farmhouse where five people were accustomed to sleep in one not very large bedroom which had only one small window, and even this was nailed shut; one of these five had incipient tuberculosis. These people were well-to-do farmers, living in a large twelve-room brick house, and simply crowded into one room for the sake of mistaken economy—presumably to save coal and wood.

Another phase of this kind of overcrowding is apparent in certain mountain districts of Pennsylvania, and I suppose it may be very much the same elsewhere. It has been noted in these places that the natives do not have a strong, healthy build and a color redolent of health, but the thin, pale and wan features of those suffering from the lack of pure air. Yet these people live in the purest of God's fresh air, in places akin to those where we build our sanatoria. Why is it? The explanation seems to be dependent on the personal habits of these mountaineers, who on the advent of winter

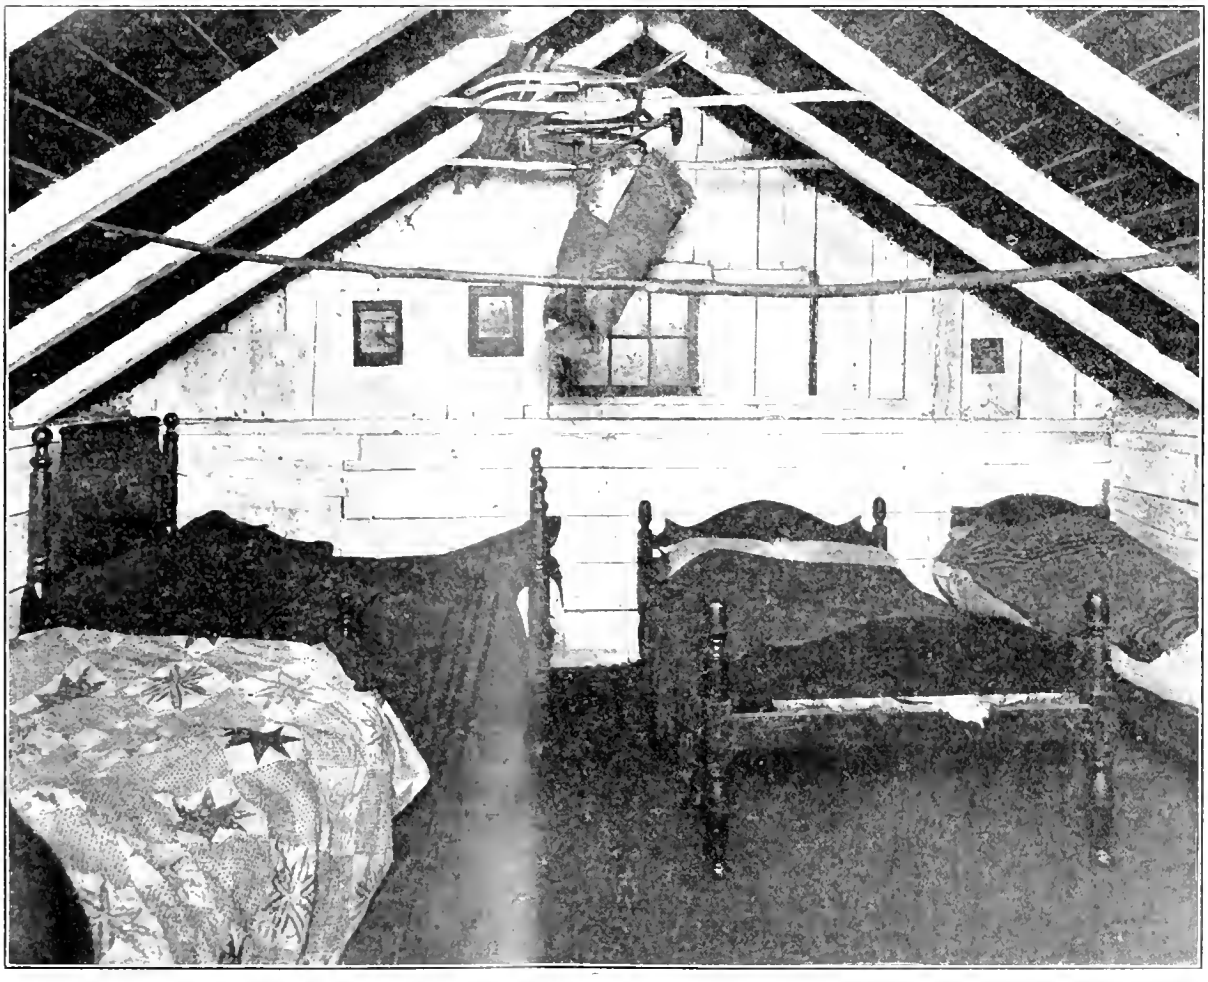

Fig. 2.—This bedroom (15x15 ft.), the [illegible] the house shown in Fig. 1, was used habitually by eight persons.

"hole-up," a good deal like certain animals. They lay in a supply of wood, but as wood is becoming scarce, and they are generally lazy and shiftless, the supply is not ever abundant, so they economize space and heat and have fire only in the cook stove. Windows and unnecessary doors are nailed shut, and here around the stove they spend most of the winter, eat and sleep in one, or at the most, two rooms; and the result? The faces you see in these mountain homes remind you of the faces you see in the densely crowded insanitary tenements of the cities. The complete outdoor life of summer is barely able to combat the bad air and the lack of air during the winter months, and a chronic condition of lowered vitality results.

The worst case of overcrowding of this sort, or of any sort, that I have ever seen appeared one day last summer when I prepared to administer immunizing doses of antitoxin to an Italian family during an epidemic of diphtheria; thirteen children lined up to "take their medicine;" in addition there were six adults, making nineteen human beings living in one house, and this house containing only six rooms. Where these people slept was almost a mystery, for there were only three beds in the house. They simply stretched out on the floor, and their pale and sallow faces told the cost, the great cost of overcrowding. You might think this was a Hester street tenement, but it happened to be a farmhouse, situated in one of the most beautiful valleys of Southern Pennsylvania, far from the smoke and din of cities.

When such conditions exist as I have described, and they certainly do exist in Pennsylvania, is it not time to endeavor to educate the people in the country, as well as in town, to better housing conditions? The old idea that the country is such a healthy place to live in is good only so far as the country is fresh from the hand of the Lord, for man's make-over in the country is generally poor, very poor. Not only does the native and the tenant need looking after but also the landlord, the careless and thoughtless landlord. Only by education can such conditions be overcome, and when they are overcome we will have made a great step toward right living and towards the elimination of that dread disease—tuberculosis.

REPORT OF CASES.*

By FORBES R. McCREERY, M.D.,

NEW YORK.

I. PERFORATION OF THE CECUM BY A FECAL CONCRETION, PROBABLY FORMED IN A DIVERTICULUM.

Mrs. W., æt. 35, primapara. The patient's previous health has been good except for habitual constipation. She was seen April 22, 1911, and gave a history of pain in the upper part of the abdomen four days before. This recurred in the epigastrium on the 21st. There was nausea but no vomiting. The pain later became localized on the right side. Menses came on April 20, five days before they were due.

On examination the left side of abdomen was seen to be relaxed, the right side only moderately tense. There was a mass a little above McBurney's point. No lesion of gall-bladder or kidney could be made out. Uterus retroverted; no other pelvic lesion. Temperature 101°, pulse 108. A diagnosis was made of appendicitis with abscess, probably retrocecal, and with a high location possibly due to an undescended cecum.

I operated that afternoon through a high intermuscular incision. The cecum presented, but the mass was still higher. The cecum was drawn out of the abdomen with moderate difficulty, bringing with it the mass. In the process the adhesions gave way, with the escape of about ½ ounce of thin, foul pus. Lying at the base of the small abscess cavity was a concretion protruding through a ragged hole in the gut. The entire mass in the lower end of the cecum was now well outside the abdomen. The appendix, which was the last to come, was normal. The concretion was removed and proved to be hardened feces the size and shape of a lima bean. It protruded through a hole in cecum between the anterior longitudinal band and the mesocecum and 1½ in. above the base of the appendix.

The wall of the cecum together with the mesocecum was so thick and soft that every other stitch employed in the attempt to enfold the gut cut through, necessitating a second row of stitches, going through the anterior longitudinal band. Of these, about one in three cut through. A third row, going well outside the anterior longitudinal band, was more successful. As the vitality of the gut was very doubtful, and I feared a fecal fistula, I split the peritoneal coat of the appendix opposite its mesenteric attachment, stripped it from the muscularis and turned it up over the suture line, tacking it down with fine catgut stitches. The balance of the appendix was then removed, and the wound closed, with drainage.

Convalescence was satisfactory; the drains were removed within a week. There was no fecal fistula, but a sinus discharging a drop or two of pus persisted until August 14. This was due to the sutures, all of which came out one by one during the summer. The concretion had probably formed in a diverticulum of the cecum, similar to those more commonly occurring in the sigmoid, but no trace of such supposititious diverticulum was noted.

II. FRACTURE DISLOCATION OF THE CUBOID—REPORT OF A CASE WITH *X*-RAY PHOTOGRAPH.

C. M., æt. 50; male; carpenter. August 8, 1911, a plank on which he was standing broke and he

fell about 6 ft. and on attempting to rise he found the anterior portion of his foot bent inwards at right angles to its normal position. He caught it and pulled it back into position, it going back with

*Read before the Surgical Section of the New York Academy of Medicine, February 2, 1912.

a distinct snap. When I saw him a few hours later the foot was badly swollen, but there was no distortion. An *x*-ray photograph taken by Dr. Cole showed a fracture through the cuboid, probably tearing a thin layer of the cortex from the cancellous portion of the bone. I judge that the fracture permitted an inward dislocation of the distal portion of the tarsus. The foot and leg were put up in plaster of paris and the ultimate result was satisfactory.

123 East Fortieth Street.

ORCHITIS WITH UNUSUAL FEATURES.

By L. BOLTON BANGS, M. D.,

NEW YORK.

The following case illustrates some of the difficulties of diagnosis in diseases of the testicle and has features which are unusual. The patient is an unmarried man aged 41, who, with the exception of typhoid fever and some neurasthenic attacks, has had no illnesses till the present. He has been subjected to severe mental and emotional strain and has led a strenuous business life. In his immediate family there is a history of tuberculosis. There is no venereal history and there are no symptoms of urinary disturbance.

In May, 1911, he received a slight blow on the right testicle. His memory of the cause and force of the blow is uncertain, but a slight swelling of the upper lobe of the epididymis resulted and persisted. He drove his motor car considerably during the summer and this always caused pain in the swollen epididymis. In August, during a match game of tennis, he struck the same testicle with the handle of the racquet, which caused increased swelling and pain. Subsequently, during a horseback ride the same organ was struck against the pommel of his saddle, which traumatism, although apparently insignificant, caused a marked aggravation of the pain and an increase in the swelling. A suspensory bandage relieved it for a time, but the pain gradually increased till, on the 28th of September, it suddenly became excruciating and radiated down the inside of his right thigh and up into the right groin. On the following day he was sent to my care and came first under the observation of my associate, Dr. Frederick W. Smith, who recorded the testicle greatly enlarged, smooth, globular, tense and exquisitely tender, the latter so marked that careful examination was impossible. The cord was slightly thickened and examination by the rectum showed that the prostate gland was slightly enlarged, smooth and insensitive. The patient was put to bed in the hospital, the testicle supported and antiphlogistine applied. He had a slight rise of temperature (to 99 3/10°), which persisted for six days. The whole condition seemed to be one of sub-acute inflammation, but the pain was enough to prevent sleep and an anodyne was required. Five days later I saw him for the first time and the pain being still very severe, hot flaxseed poultices were ordered, which gave great relief immediately, and he was able to sleep without anodynes. The poultices gave him so much comfort that he asked for a continuation of them, and three days later it was possible to palpate the organ with more accuracy. The epididymis could be differentiated from the body of the testicle, but, although palpation determined that the epididymis was nodular and enlarged to three times (perhaps more) than normal, it was still so very sensitive that its exact condition could not be defined. At this time the body of the testicle was also somewhat enlarged, globular, smooth, non-fluctuant and very tender. The tunica vaginalis seemed to be thickened to careful palpation. There were no enlarged glands. The poultices were now stopped, but pain on sitting up or on locomotion was so notable that he was kept in bed with the testicle supported. But the swelling did not diminish, on the contrary the whole organ slowly increased in size, and becoming more and more painful and tense, ten days later (October 12) a puncture of the tunica vaginalis was made. A little serum escaped, so little, that the tunica albuginea was incised. This relieved his pain immediately. He was able to get out of bed, to move about, and ten days later to leave the hospital and to come to the office for treatment. Although the pain had been relieved to large degree it was still present, subacutely, and the swelling and tenderness of the organ persisted. At the site of the puncture in the anterior surface of the scrotum gradually a fungus-like circle of granulations appeared. At no time had the diagnosis been clear. But taking into consideration that the disease was not gonorrheal; that it had begun in the globus major of the epididymis after a slight traumatism, and that it had pursued a subacute, slow and persistent course, a tentative diagnosis of tuberculosis was made. Furthermore, as for two weeks the testicle had remained about the same, showing no tendency to diminish, being (say, ten times the size of the left one) smooth and elastic, and although still painful and tender, these symptoms being less marked, it was decided to test the patient with subcutaneous injections of tuberculin. He received one injection (of Mulford's No. 1 serial) when he complained so strongly of pains all over, in back, hips and down his right leg and an increase of pain in the testicle, that, after another injection, tuberculin was discontinued, and he was sent to Dr. Cole for a radiograph. This did not reveal anything especial, and gave no diagnostic help. The whole testicle continued slowly to increase, and though the patient's history excluded syphilis, the cardinal rule in doubtful cases was obeyed and he was given hydrargyrum and potiodid with the intention of adding increasing doses of the latter. Meantime, the scrotum had become dusky, or purplish red, and on the inferior end a soft protuberance had been forming. This was tender, elastic, and apparently fluctuating. It was aspirated with an exploring needle and a bloody fluid withdrawn, which was sent to the laboratory for report, as follows:

Report No. 1. The smears consist of little blood cells mixed with a large amount of epithelia, large, flat and small round together with a moderate number of leucocytes. Increase in the number of the latter is indicative of congestion, but there is nothing to indicate inflammation (pus). The smears were searched thoroughly for tubercle bacilli with negative results. No other bacteria present.

The patient then went to his home in a distant town and on his return four days later there had been such a notable increase in the size of the testicle with augmentation of pain, that I advised immediate orchidectomy. This I performed on the following day, November 11. The incision encompassed the fungus opening on the anterior surface of the testicle. The tunica vaginalis was found to be very much thickened and its parietal and visceral surfaces were agglutinated. These were easily separated by the tips of the fingers, and

as the separation was finished a strange thing happened. The testicle dropped out of its sac into my hands like a ripe apple from its stem. No force had been used. There had been no dragging or twisting of the organ which had rested on a platform of sterile towels during the operation. There was no bleeding from the stump of the cord, but on nicking one of the veins about two inches above it bled freely. The vas deferens was identified and each element of the cord separately and carefully examined, but no pathological condition could be recognized. The entire tunica vaginalis was completely dissected from the tissues of the scrotum and sent with the testicle to Dr. Higgins for examination. For three days the patient had a rise of temperature to 100.3°, after that convalescence went on smoothly with the exception of a slight serous discharge from the lower angle of the wound where a cigarette drain had been placed. The pathologist's report follows with his comments.

"EXAMINATION OF TISSUE.

"1. Round mass, presumably testicle, 3¼ inches long by 2½ inches in the shorter diameter. The outer surface is dark red in color and somewhat uneven and here and there are a number of soft, white, slightly elevated areas filled with thick, creamy fluid. The organ is very soft and exudes on pressure a slight brown sanious fluid. Posteriorly, in about the middle, there is an irregular cavity about ¾ of an inch in depth. Extending upwards from this cavity is a ridge of tissue about one inch in width similar in appearance to the body of the specimen.

"2. Part of the tunica albuginea, the wall of which in places is about ½ inch thick.

"3. A thickened portion of the scrotum surrounding a short patent canal.

"MICROSCOPICAL EXAMINATION.

"The mass is bordered by a narrow congested layer of fibrous tissue from which broad trabeculæ of loose fibrous structure extend, dividing the organ into irregular cavities of varying size. Most of the cavities or lobules are large and of very irregular outline. Some are lined or partly lined with one or two layers of swollen, flattened, or cylindrical epithelium, but as a rule the epithelial lining of the lobules has been desquamated and lies in rows or plaques free in the cavity, which is crowded with many single, swollen, epithelial cells, cell nuclei, polynuclear and small round cells, masses of red blood cells and fibrin. In places the fibrous framework has broken down, forming very large cavities distended with blood and desquamated epithelium. The fibrous tissue, especially around the outer surface, is deeply congested and infiltrated to a moderate degree with polynuclear cells and lymphocytes. Sections from the thickened ridge traversing the posterior surface of the organ show a loose, vascular, fibrous framework densely congested and infiltrated with small, round, plasma and polynuclear cells and include a number of cross sections of the epididymis. The lumina of the latter are clear except for a few free red blood cells. In sections taken from the epididymis near to the cavity mentioned above, there are quite a number of minute areas filled with polynuclear and lymphoid cells.

"In the sections taken from the other end of the epididymis the infiltration is more of the chronic type, most of the cells being small, mononuclear, plasma or epithelioid with relatively few polynuclear cells.

"No. 2. The fibrovascular capsule (tunica albuginea) is deeply congested and densely infiltrated with many lymphocytes and plasma cells together with relatively few polynuclear cells. The inflammation here is acute, superimposed upon a chronic process.

"No. 3. Sections from the scrotum show deep congestion and acute inflammation.

"Diagnosis: Acute inflammation following contusion of the testicle with large blood effusions and laceration of the tubules; acute epididymitis superimposed upon chronic epididymitis.

"From the examination of the specimens, my opinion is that there has been a chronic epididymitis which developed into an acute epididymitis and orchitis following the contusion. The epididymitis was of the simple chronic form. At least, in none of the sections can I find any indication of tuberculous infection.

"According to the classification of one author, the contusion is of the second degree, the classification depending upon the extravasation into and the destruction of the tubules. As to why the testicle was found free in the cavity, I am unable to advance any reasonable opinion."

40 EAST FORTY-FIRST STREET.

Multiple Cephalhematomata.—Vernon and Marcomet report the case of an infant born after a breach labor in whom there were three cephalhematomata, one on each parietal bone and one on the occiput.—*Lyon Médical.*

Hypophysary Opotherapy.—H. Pater says that the idea of the internal secretion of certain glands explains many clinical, therapeutical, and experimental facts otherwise hard to understand. The administration of the extract of one of these organs exaggerates or modifies the work of other organs of different names, and exalts the work of those of the same name. An opotherapeutic product has always two actions; a direct and an indirect action. With direct action we fight against hypophysary insufficiency; in indirect opotherapy we struggle against pluriglandular insufficiencies. The experimental action of hypophysary extract is double: first on the hypophysis of the animal treated; second on other organs of its body. The extract of the entire hypophysis causes an increase of arterial tension, slowing of the pulse, and increase in the amplitude of the heart beats. A series of injections of this substance causes a hypertrophy of the hypophysis, congestion, abundance of eosinophiles, presence of much extracellular colloid material, and a secretory hyperactivity. The thyroids show a prolonged vasoconstriction, lessening of substance and of secretion. The suprarenal capsules have an exaggerated action; undergo hypertrophy and hyperplasia. The kidneys present vasodilation and polyuria. Disease of the hypophysis causes acromegaly. The extract of hypopyhysis may be used therapeutically to raise arterial tension, slow the pulse, increase diuresis, prevent painful feelings of heat and sweating, increase appetite and sleep, lessen asthenia, and psychic troubles, increase the development of the bones and muscles, and play an antitoxic rôle. Its uses are substitutive in case of imperfect function of the hypophysis; it may be used to increase resistance in a series of serious infections, typhoid, diphtheria, pneumonia, etc., where the myocardium fails and there appears an acceleration of the pulse, lowering of arterial tension, lessening of kidney secretion, etc. It is useful in acute and in chronic cardiopathies, in nervous tachycardia, in insomnia with hypotension, in uterine hemorrhages, in intestinal atony, and in surgical shock.—*Bulletin Général de Thérapeutique.*

New York, March 2, 1912.

RECENT DEVELOPMENTS IN THE PHYSIOLOGY, PATHOLOGY, AND SURGERY OF THE THYMUS.

For many years there have been recognized two distinct types of thymus pathology, namely, the so-called "mors thymica" and thymic asthma. The vital significance of the thymus has been revealed by the researches of Klose and Vogt into the causation of the *cachexia thymopriva* and *coma thymicum*, which researches have already been alluded to in these columns. A further contribution to this important subject has recently been made by D. Sokoloff in the *Archiv für Kinderheilkunde*, December 23, 1911. As the result of clinical and experimental studies this observer notes that under normal conditions the thymus continues to develop until the twelfth to the fourteenth year of life, the maximum increment of growth occurring at the sixth year. The involution of the gland is characterized by a fatty and a connective tissue degeneration, and even in advanced age the gland is still in evidence, though not in the sense of a functionating organ. The thymus stands in reciprocal relationship to the nutrition of the child, becoming atrophic in conditions of malnutrition. Extirpation of the gland in animals causes an increase in the number of red blood cells and apparently no other marked changes in the organism. This observation is directly at variance with those made by Klose and Vogt, who noted following thymectomy in dogs a resulting cachexia culminating in coma and death, and in human beings retardation and deficiency in osseous development, degenerative changes in the nervous system, and a tendency to obesity, all of which changes are attributed to an acid intoxication, chiefly with nucleinic acid. Sokoloff finds that the thymus is closely related in its activity to that of the spleen, testis, and thyroid, but chiefly with the function of the last-mentioned gland. The injection of the expressed juice of the thymus into animals may result fatally, after causing a fall in blood-pressure and a slowing of the pulse. Thymus extract has apparently no antitoxic effect, at any rate with reference to the diphtheria poison. In many cases in which thyroid feeding is of value the administration of thymus is also efficacious. Sokoloff advances the view that while the thymus is a gland whose internal secretion takes part in the metabolic activities underlying growth, nevertheless this function is also shared by other glands.

As regards the cases of sudden death that have been attributed to thymus hyperplasia, Sokoloff maintains that the lethal outcome in these cases is not the direct result of the enlargement of the thymus, but is caused by a disturbance of the bodily metabolism, of which the hyperplasia of the thymus as well as of other glands is but one manifestation. Thymic asthma, caused by the pressure on the trachea of the hypertrophied gland, is a definite pathological entity, but it should not be confused with other forms of asthma, chiefly with that resulting from tracheobronchial adenopathy. In making a diagnosis of thymic asthma it is necessary also to exclude the respiratory difficulties resulting from obstructions in the nose and nasopharynx, from enlargement of the tongue, hypertrophied tonsils, and adenoids, laryngeal stenosis, congenital laryngeal stridor, and from obstructions in the upper and lower parts of the trachea, and in various parts of the bronchial tree. One constant characteristic of thymic asthma is the fact that the dyspnea is expiratory.

The treatment of thymic hypertrophy presents problems that are exclusively surgical. These problems are attacked by Eugène Olivier* in a recently published monograph on the topographical anatomy and surgery of this organ. This writer notes that three different operative procedures have been devised for the treatment of thymic hypertrophy, namely, exothymopexy, resection of the manubrium sterni, and thymectomy. The first of these operations consists in freeing the thymus from its normal attachments, either wholly or partially, and fixing it in a high position to the infrasternal fascia. This operation is rejected by the author as being both difficult and dangerous, and for the same reason the operation of resection of the manubrium is condemned. Thymectomy, which is the operation of choice, may be accomplished most easily by means of subcapsular enucleation. The author has collected from the literature thirty-nine cases of thymectomy in which there was a mortality of fifteen. Of these deaths five were caused by infection consequent on drainage or the performance of a tracheotomy, four were caused by an error of diagnosis (the cases being instance of tracheobronchial adenopathy), three were due to the desperate condition of the infant before operation, one was caused by bronchopneumonia, and one by enterocolitis. It is concluded that a simple thymectomy, without drainage and without the performance of a tracheotomy, has a mortality practically nil.

ATHLETICS IN THE NAVY.

According to the annual report of the Surgeon General of the Navy the health of the navy during the year 1910 appears to have been satisfactory. The death rate from disease was slightly higher than in the previous year, but was below the average rate. The death rate from injuries showed

*"Anatomie Topographique et Chirurgie du Thymus," par M. le Dr. Eugène Olivier, Ancien Interne des Hôpitaux de Paris; d'Anatomie à la Faculté de Médecine. Avec 16 figures et 2 radiographies. Paris: G. Steinheil, 1911.

an increase over 1909 and was in excess of the rate of the "average year." The increase in the death rate was due to the large number of deaths from drowning. There was, however, a reduction in the total damage from disease and injury in the service indicating an improvement in the general health of the entire Navy and Marine Corps.

One of the most interesting parts of the report is that referring to athletics. It states that the bureau is of the opinion that competitive and spectacular athletics is undesirable in the service, especially among midshipmen, who are prone to overtrain for or hazard too much in a contest. It is pointed out that the function of the Naval Academy is to equip young men mentally and physically for their chosen profession. It is considered, therefore, that physical training and athletics generally should be indulged in so as to safeguard the interests of the Government and the individuals as well. The surgeon-general says with regard to football that "while football may be somewhat hazardous as played, it is the disabling after effects that in my opinion, make it questionable as a sport to be encouraged where future naval officers are being trained." The writer recapitulates the views of some authorities that the prolonged rigorous course of physical exercises necessary to excellence in physical sports is dangerous in its after effects upon those who indulge in athletic sports sufficiently to excel therein. Further, it is suggested that under the conditions of service at sea, as it becomes impossible to continue rigorous exercise, the individual will easily fall prey to degenerative changes, will tend to become obese, to lose physical stamina, and in the end will fail to render as many years of efficient service under service conditions as will the less athletic, but symmetrically developed classmate. Statistics are quoted to prove the contention that athletics carried to excess or severe training undertaken under unfavorable conditions does not conduce to long life or good health. The opinions of those in civil life best qualified are stated to be in agreement with these views, and finally a change in the methods of training and of conducting athletics generally at Annapolis is recommended. The custom now of employing professional coaches and trainers at the Naval Academy is sharply criticised. It is urged that the chief end and aim of such trainers is merely to produce winning teams, as upon this depend largely their reputation and occupation. It would be better from all points of view, thinks the surgeon-general, if graduates of the Naval Academy, with specially detailed medical officers, displaced professional trainers, and he is of the opinion that the importance of the subject would justify the assignment of such officers for the purpose.

Whatever may be the views of medical experts in training and athletics and of the medical profession generally the position of the surgeon-general and his many opportunities for studying the matter closely entitle his opinions to be received with respect and consideration. The question of athletics and training as now conducted is a vexed one and there is little agreement on the subject among either members of the profession or the laity

SANITATION OF LAUNDRIES.

No little attention has been directed of late to the matter of the hygiene and sanitation of laundries. An investigation which has been begun by the Consumers' League of New York City is of interest in this regard. The League's inspectors have so far visited 40 of the larger steam laundries. No small laundries or Chinese laundries have yet been inspected. Practically all of the laundry work for New York City is done by large steam laundries, the small so-called hand laundries acting merely as receiving stations and occasionally doing part of their own ironing. All of the clothing is divided into the two classes of colored and white goods. Each of these is made up into large bundles enclosed in a net. Colored articles from all patrons are put together, and white articles the same. The chances of a spread of contagion among the patrons from clothing which may be soiled with syphilitic or other secretions, or infected with the germs of typhoid or tuberculosis are not great since the subsequent treatment probably sterilizes the clothing; but there is a rare opportunity for the laundry employees to contract these diseases, as has occurred in several instances already reported, and probably in many more not reported.

As for conditions in the laundries themselves, certain features were found deserving of the severest reprobation. A common finding was most offensive toilet facilities for both male and female employees. Often there was no proper separation of waterclosets from the rooms in which the clothing was being treated and the odor from the closet was overpoweringly offensive. Filth, and rotten, leaky plumbing were the rule in these toilets. In many washrooms poor ventilation and leaky steam pipes were responsible for a highly overheated atmosphere loaded to the point of saturation with water vapor. The attendants in these rooms often stood and worked in water inches deep. This condition explains why rheumatism is so common among laundry employees as to deserve the appellation of an industrial disease peculiar to this trade. In the starching rooms indescribably filthy floors were found, caked deep with starch and dirt. In one instance the stables were on the same floor with the wash rooms, and the stable odors and flies filled the laundry.

The Consumers' League is preparing a white list of laundries which, in a fair measure, meet the requirements of the League. These lists will be supplied to all laundry patrons on request. White list laundries will be those in which decent retiring rooms and toilet facilities are provided for employees; where working hours are not excessive; where machinery is well guarded to prevent accident, and where cleanliness and sanitary conditions prevail. Physicians have a very definite responsibility in all that comes under the heading of preventive medicine, and few fields here are of more importance than proper regulation of industrial hygiene, from the standpoints both of the patron and of the employee. The earnest effort being made by the Consumers' League to improve laundry condition deserves the hearty cooperation of all.

The Discretion of the Surgeon.

A decision recently given in a suit brought against a prominent surgeon of this city for "trespass and assault" is of more than ordinary interest and importance in its bearing upon how far a surgeon may be allowed to use his discretion in dealing with unforeseen circumstances arising during the course of an operation. The facts of the case are, briefly, as follows: In the fall of 1908 the surgeon performed a cholecystectomy on a patient, from which she recovered nicely. Half a year later she returned, having been sent by her physician with the diagnosis, appendicitis. Careful examination prompted the surgeon to tell her that he could not say definitely whether her appendix alone was at fault, but that he would make his incision in such a way that he could examine also her pelvic organs. She replied, "Doctor, you saved my life once; I leave it to you to do what is best for me." Two days later she was operated upon. After removal of the greatly inflamed and adherent appendix, the tubes and ovaries were examined in high Trendelenburg posture. On the right side the appendages were found adherent to the posterior aspect of the much enlarged uterus, about one inch below the level of the fundus. They were loosened and put in normal position. When about to close up the abdomen, the operator saw on the opposite side a peculiar gelatinous mass which, on palpation proved to be the diseased left ovary, which needed extirpation. A median incision was made and the chronically inflamed ovary—evidently a chronic abscess encased in adhesions of old standing—was removed with difficulty. Seventeen days later the patient left the hospital, cured. Six months later she brought suit for $10,000 damages for "trespass and assault," and two years later, her husband brought suit for the same amount and for the same cause. At the trial the above history was given to the jury and four experts corroborated the correctness of the surgeon's conduct. Of course, it was not a suit of malpractice or unskilful operating, but merely a question as to whether the operator had done his duty as a conscientious surgeon in removing the organ which was an absolute menace to the welfare if not life of the patient—to which, besides, he had her consent—or whether he had overstepped his rights in the case. After both sides had been heard, the presiding justice, Judge Blanchard, dismissed the case.

Selenium in the Treatment of Cancer.

Our Berlin correspondent recently wrote of experiments by Wassermann with eosin and selenium in the treatment of mouse cancer. It was said that the remedy had proved to be positively curative in the case of malignant growths in mice, but it has not yet been tried in human cancer, at least no report of such trial has been published. As one of the drugs used by Wassermann is selenium, it is interesting to note that this has been used for the past eighteen months in New York in the treatment of human cancer, apparently with good results. In the *New Yorker medizinische Monatsschrift* for January, 1912, Eugene G. Kessler reports on the use of selenium in the treatment of cancer, claiming to have obtained very encouraging results. He was led to the use of this remedy through the observation of von Oefele and Klein that the excretion of sulphur, or sulphuric acid, in the urine was markedly diminished in cancer. Selenium, which belongs to the sulphur group, possesses the property of attracting oxygen and then giving it up again to sulphur. Kessler therefore conceived the idea that its administration in cases of cancer might contribute to the oxidation of the sulphur and so restore the equilibrium in the output of this substance, thereby effecting a metabolic change favorable to the regression of the malignant growth. Accordingly he gave it in a series of cases, one of which he reports at length. The patient was a woman, 60 years of age, who had been operated upon fifteen years ago for cancer of the breast. At the time of examination she was cachectic, the output of sulphur in the urine was greatly diminished, and the liver was enlarged and evidently the seat of a secondary cancerous growth. Treatment was begun July 27, 1910, with a milligram of selenium oxide (SeO_2) three times a day. By September 2 there had been a gain in weight of 2½ pounds and the liver dullness had receded two finger-breadths. During the treatment the patient at times gave evidence of renal irritation which the author attributed to the rapid breaking down and excretion of the cancer cells—possibly the same thing that killed the mice in the Wassermann experiments. The improvement in the general condition was, however, continuous and up to the time of the report, eighteen months after the beginning of treatment, there had been no relapse.

Pseudoneuritis Optica.

This subject has received comparatively little attention in standard works, and it is claimed that hardly any illustrations of the fundus in this affection or these affections is to be found in any atlas of the eye. The subject is of great importance, for it is not impossible that an erroneous diagnosis of choked disk might lead to a trephining. The subject naturally concerns greatly the psychiatrist, for whom anomalies of the papilla possess great significance. Sulzer, author of a monograph on true and false diagnosis of cerebral disease from the optic papilla, illustrating pseudoneuritis, has recently written a paper on pseudoneuritis (*Münchener medizinische Wochenschrift*, December 19), in which he attempts to sketch the characteristics of four distinct conditions comprised under this head. If the papilla is uncommonly red he uses the term pseudoneuritis rubra. The latter is seen in people of all shades of complexion and hair color and with all varieties of refraction. The diagnosis from true neuritis can be made only after long observation and estimation of collateral data. If there is a radiating striation of the papilla the condition is known as pseudoneuritis striata. This is a congenital anomaly, and, as in the preceding form, assertions that it occurs only with certain complexions, etc., are unwarranted. It is said to be more frequent and pronounced in negroes and apes than in whites, although it is often faintly in evidence in the latter. It is sometimes accompanied by errors of refraction, both phenomena being of the nature of slight malformations. The two other forms are known, respectively, as pseudoneuritis hyperplastica and pseudoneuritis prominens, due evidently to proliferation of glia and connective tissue. The latter is extremely rare, and, as the papilla stands out in the fundus like a button, the condition may readily be confounded with the highest degree of choked disk. The blood-vessels, however, show no alterations. The absence of enucleation or autopsy material makes it difficult to arrive at the exact nature of these conditions, so that at present we know of them only as ophthalmoscopic pictures.

News of the Week.

Contagious Diseases in New York State.—The Monthly Bulletin of the State Department of Health shows that for the month of December there were 11,032 cases, or 1,000 less than for December, 1910. Scarlet fever showed an increase in the number of cases, there being 1,480 for December as compared with 1,260 cases reported for November. There were 2,441 cases of tuberculosis reported, which was a considerable decrease as compared with the 2,692 cases reported for November. There were almost twice as many cases of measles reported for December as for November, when 1,405 cases were recorded. There were only 661 cases of typhoid fever reported during December, a decrease of 100 cases as compared with November, 1911, but a slight increase as compared with the corresponding month of 1910, when 577 cases were reported. There were 662 cases of whooping cough reported as compared with 739 cases for November. Reports were received of 166 cases of smallpox during the month of December and the State Department of Health has forwarded literature on the diagnosis of smallpox and the value of vaccination as a prophylactic against this disease to the physicians of the State and wholesale vaccination with abatement of the epidemic have been reported from several localities. During December there were 170 deaths from diphtheria, which is unusually few for this season, and the year ends with a record of less than 2,000 deaths from this cause, the fewest for any year in the annals of collated statistics of the State. In thirteen years, 1885-1897, there were in the State 71,043 deaths from diphtheria, while during the following thirteen years there have been 35,460 deaths from this cause. In other words the mortality from diphtheria has decreased one-half during the past thirteen years, while the population has increased one-third during the same time. There were 17,733 births in the State during December, 1911.

Venereal Diseases to Be Reported in New York.—At the meeting of the Board of Health on February 20, resolutions were adopted calling for the reporting of venereal diseases to the Department of Health. This is in accordance with a plan for the sanitary control of these diseases which has been under consideration for nearly a year. At the same meeting it was announced that the Board of Estimate and Apportionment had considered favorably the request for an appropriation of $55,000 for the erection of a hospital for the care of patients suffering from venereal diseases. The resolution includes a plan requiring superintendents or other officers in charge of public hospitals, dispensaries, clinics, charitable and correctional institutions, including those which are supported in part or in full by voluntary contributions, to report all cases of venereal disease applying for treatment at the institution. It is required that the name, age, sex, nationality, race, marital state, and address of every patient under observation suffering from these diseases shall be reported. All physicians are requested to furnish similar information regarding private patients though the name and address need not be given. The Board of Health will undertake to make bacteriological examinations and tests for the diagnosis of these diseases and to distribute curative sera only when the data required for registration have been furnished.

Meningitis in Oklahoma.—Meningitis seems to be spreading in southern Oklahoma, and the State Health Commission, Dr. J. C. Mahr, and the State Bacteriologist, Dr. Gayfree Ellison, have gone to Durant, Bryan County, to take charge of the situation there. Thirty-seven cases have developed in this county, 17 cases have been reported in Love County, 13 in Marshall, 11 in Osage. The disease has appeared in thirty counties and thus far there have been 157 cases with 67 deaths.

Health of the Canal Zone.—The report of the department of sanitation of the Isthmian Canal Commission for the month of December, 1911, shows that the total number of deaths from all causes among employees was 44. Of these 24 were due to disease, and 20 to violence, giving an annual average per thousand of 5.68 and 4.74 respectively. In segregating, according to race, the annual average death rate per thousand from disease among employees was for whites 5.71 and for blacks 5.68, giving a general average for disease of 5.68. For the same months of 1909 the annual average death rate per thousand from disease among whites was 8.39 and blacks 10.67, giving a general average of 10.13; and in 1910 from disease among whites 5.69 and blacks 8.79, giving a general average of 7.94. No cases of yellow fever, smallpox, or plague originated on or were brought to the isthmus during the month.

Tuberculosis Among Alaska Indians.—Dr. M. H. Foster, Passed Assistant Surgeon in the Public Health and Marine-Hospital Service, who was sent to Alaska to make a survey of conditions, has presented his report which, although accurate statistics are not available, shows that unless the Government takes prompt measures to protect the Indians, none will be left in the course of two or three generations. At Sitka accurate records have been kept by the churches and they show that for a period of five years and seven months the annual birth rate has been 72.3 per thousand and the annual death rate 85.4 per thousand. During this period, with an estimated population of 400, there have been twenty-nine more deaths than births. In the last ten years the United States Census Bureau reports that the Indian population has decreased 14 per cent.

Lepers in New York.—The death of a West Indian negress, who for a year and a half has been a member of the leper colony on Blackwell's Island, has occasioned some discussion on the part of the public as to the communicability of this disease. It is reported that one physician has seen as many as thirty cases of leprosy in New York during a single year, and that there are known to a few physicians a number of individuals who have suffered from leprosy for many years and still pursue their lives as usual without communicating the disease to any of those with whom they are thrown in contact. New York physicians, for the most part, believe that the fear of this disease in this climate is entirely unwarranted and that the public should be informed of this fact, as the fear of leprosy is more of a danger to the community than the few cases of the disease in itself. In this connection the case of the fifteen-year-old school boy whose examination at the Massachusetts General Hospital in Boston last June which revealed the presence of leprosy is of interest. Since that time the boy has lived a life of complete isolation from his kind and now the Federation of Women's Clubs of Massachusetts is petitioning the Legislature that the boy be accepted as one of the Penikese Island Colony. The boy had

the disease for four years during which time he was in constant attendance at school and there is no evidence that he has been the cause of any of the cases of the malady.

Medical Practice Act in Massachusetts to Remain Unchanged.—The Committee on Public Health has reported to the Senate that no legislation is necessary on the recommendations contained in the report of the Board of Registration in Medicine. These recommendations sought to define the practice of medicine and to do away with the exemptions which some irregular practitioners enjoy. These would if enacted into law have made the practitioner of Christian Science liable to fine and imprisonment.

Vaccination Statistics Called For.—The Medical Society of the County of Erie at its annual meeting passed resolutions stating that whereas there had been 297,288 cases of smallpox in America during the past decade and whereas the mortality and morbidity of smallpox were rapidly increasing, probably owing to the propaganda of antivaccinationists, a request be sent to all city, State, and national authorities urging them to take suitable action to provide that hereafter in reporting smallpox, mention and record should be made of the fact, time, and efficiency of vaccination and revaccination in every case.

Vaccination Statistics from the Philippines.—The following statistics are interesting as showing how smallpox has been practically eradicated from the United States Army in the Philippines.

Year.	*Troops.*	*Cases.*	*Per 1,000.*	*Deaths.*	*Per 1,000.*
1898	9,908	76	7.67	21	2.12
1899	30,280	267	6.80	78	1.99
1900	66,549	246	3.68	113	1.69
1901	59,526	85	1.43	37	.62
1902	37,768	63	1.67	12	.32
1903	23,818	27	1.13	3	.13
1904	11,996	4	.33	2	.17
1905	11,057	3	.27	0	.00
1906	12,622	3	.24	1	.09
1907	11,712	1	.09	0	.00
1908	12,130	2	.17	0	.00
1909	12,844	0	.00	0	.00
1910	12,277	2	.16	0	.00

Smallpox is constantly present in Manila and several cases occurred in the army within four days from the time the troops were landed in 1898. The large number of cases occurring during the first four years of American occupation was due to the fact that many of the men were volunteers and it was difficult to enforce vaccination and also because the vaccine brought from San Francisco and Japan became inactive in the warm climate of the Philippines. In 1900 the Board of Health of Manila produced fresh lymph from carabao calves, the excellent results of which were immediately effective, as is shown by the great drop in the number of cases the following year.

Texas Wants Government Land for Sanatorium Site.—An amendment to the army appropriation bill has been adopted which leaves to the discretion of the President and the Governor of Texas whether any part or the whole of the government reservation of 640 acres now used for army barracks and government buildings be given to the State of Texas for a tuberculosis sanatorium or not. The belief prevails, however, that the entire tract will be donated to Texas.

State Medical Society Favors Army Canteen.—The Massachusetts State Medical Society has passed resolutions favoring the restoration of the army canteen and has sent circulars to the Massachusetts delegation in Congress advocating the reestablishment of the canteen.

Dr. S. Weir Mitchell gave the principal address at the exercises commemorating the thirty-sixth anniversary of the founding of Johns Hopkins University, which were held at the University on February 22. After his address Dr. Mitchell was presented with the degree of Honorary Doctor of Laws.

Dr. Richard C. Cabot is mentioned as the probable successor to Dean Henry A. Christian of the Harvard Medical School, whose resignation has been accepted.

Dr. George E. Kline of Ann Arbor, Mich., has been elected superintendent of the Danvers, Mass., State Hospital to fill the vacancy caused by the resignation of Dr. Harry W. Mitchell, who has accepted a position at the Pennsylvania State Hospital at Warren.

Dr. Alvah H. Doty has been elected a member of the medical advisory board of the New York Health Department.

Dr. William James Mayo of Rochester, Minn., received the degree of Doctor of Laws at the anniversary celebration of the University of Pennsylvania on February 22. At the same time Dr. Alexander C. Abbott, Professor of Hygiene in the University of Pennsylvania, received the degree of Doctor of Hygiene from the University.

Dr. F. K. Ainsworth of San Francisco, chief surgeon of the Southern Pacific Company, has resigned his position as member of the State Board of Health.

A New Italian Hospital for New York.—A site has been purchased between Eighty-third and Eighty-fourth Streets and fronting on the East River on which it is proposed to erect a six or seven-story hospital building that will accommodate 600 patients. The cost of construction is estimated at $1,000,000, and while the hospital is intended primarily for Italians, it will not be restricted.

A Hospital for Selma.—The Memorial Hospital Company of Selma has been incorporated and has a capital of $10,000 with which it proposes to build a new hospital.

Lectures for St. Rose's Home.—A course of five lectures will be delivered at the Hotel Plaza during Lent by Dr. James J. Walsh, the proceeds of which will be devoted to paying for the completion of St. Rose's Free Home for Cancer Patients in Corlears Park, on the lower East Side of New York City.

Gifts to Hospitals.—The twelve-day campaign for the Muhlenberg Hospital of Plainfield, N. J., has netted the sum of $132,176.—The proceeds of the German Charity Ball, held at the Hotel Astor in New York, on January 25, netted $10,697, which was distributed as follows: German Hospital and Dispensary, $2,000; St. Mark's Hospital, $1,250; St. Francis Hospital, $1,250; German Poliklinik, $1,250; German Society, $1,250; Isabella Home, $950. Smaller amounts were distributed among several other institutions. The Hospital Saturday and Sunday Association of New York announces that it has collected $2,455 from several trades, which will be added to the annual hospital fund.—By the will of the late Caroline Thomas the sum of $5,000 is bequeathed to the Children's Homeopathic Hospital of Philadelphia, and a like sum to

the Children's Seashore Home at Atlantic City, N. J.

Harvey Society Lecture.—The tenth lecture of the present course will be given at the New York Academy of Medicine on March 3, at 8.30 P. M. The speaker will be Prof. H. S. Jennings of Johns Hopkins University, who announces as his subject "Old Age, Death, and the Meaning of Conjugation in Lower Animals."

"The American Practitioner."—The *American Practitioner and News of Louisville*, and the *New England Medical Monthly* and *Annals of Medical Practice* of Boston have been purchased by Dr. John W. Wainwright of this city and will be consolidated under the title of *The American Practitioner*. The new journal will be published monthly under Dr. Wainwright's editorial charge.

The Association of Medical Officers of the Militia of Canada will hold its fifth annual meeting in Ottawa on February 28 and 29.

Lectures at the New York Skin and Cancer Hospital.—A course of lectures will be given in the out-patient hall of the New York Skin and Cancer Hospital on Wednesday afternoons at 4.15 o'clock from March 17 to April 24. Dr. L. Duncan Bulkley will deliver the first six lectures on "Diet and Hygiene in Diseases of the Skin," and Dr. William Seaman Bainbridge will deliver the last lecture of the series on "Some Recent Methods of Treatment for Malignant Skin Diseases." Each lecture will be preceded by a half hour clinical demonstration. These lectures will be free to the medical profession.

Civil Service Examinations for State Hospital Positions.—Announcement is made that an examination will be held on March 23 for the position of Medical Superintendent, Matteawan State Hospital for the Criminal Insane; this position offers $3,000 to $4,500 and maintenance. There will also be an examination for Woman Physician, State Hospitals and Institutions, at the same time. For blanks and further details application may be made to the State Civil Service Commission, Albany, N. Y.

A New State Laboratory for Texas.—A State laboratory for the manufacture of antimeningitis serum, diphtheria antitoxin, typhoid fever serum, and smallpox vaccine is to be established in Austin. The United States Marine-Hospital Service will furnish an expert to supervise the manufacture of the serums and vaccines and the State will be represented by Dr. S. N. Key, State bacteriologist.

The Stephenson County Medical Society, which met at Freeport, Ill., on February 15, elected the following officers: *President*, Dr. R. J. Burns of Freeport; *Vice-President*, Dr. Sarah E. Hewetson of Freeport; *Secretary*, Dr. J. Sheldon Clark of Freeport; *Treasurer*, Dr. N. C. Phillips of Freeport; *Board of Censors*, Drs. Allen Salter of Lena, Mary L. Rosenstiel, and W. B. Peck, both of Freeport.

The Fourth Councillors District Medical Society of North Carolina met in Wilson on February 15 and elected the following officers: *President*, Dr. L. D. Wharton of Springfield; *Vice-President*, Dr. W. H. Smith of Goldsboro; *Second Vice-President*, Dr. W. H. Anderson of Wilson; *Secretary-Treasurer*, Dr. M. M. Saliba of Wilson.

Obituary Notes.—Dr. JAMES GERRIE died at his home in Brooklyn on February 10 at the age of 75. He was born in Canada and was graduated from the New York Homeopathic College in 1868.

Dr. EMERSON B. POTTER of Newton, N. J., died in a private hospital in New York, February 15. He was a graduate of the College of Physicians and Surgeons of New York City and also of the New York Homeopathic College. He was 55 years old.

Dr. ROBERT C. WHITE of the United States Marine-Hospital Service, a graduate of the University of Louisville, Medical Department, in 1855, died in Pensacola, Fla., after a protracted illness February 17, at the age of 70 years.

Dr. WILLIAM S. RICHARDSON of Marlboro, Mass., a graduate of Medical School of Harvard University, Boston, in 1884, died suddenly at his home February 9.

Dr. FRANKLIN NICKERSON of Lowell, Mass., a graduate of Medical School of Harvard University, Boston, in 1863, died at his home February 15, at the age of 73 years.

Dr. JOSEPH J. JOHNSON of St. Matthews, S. C., a graduate of Louisville Medical College, Ky., in 1888, died suddenly at his home February 9, at the age of 55 years.

Dr. JOHN D. W. HENDERSON of Philadelphia, Pa., a graduate of the University of Pennsylvania, Medical Department, in 1901, died at his home of heart disease February 13, at the age of 72.

Dr. WILLIAM W. KIRBY of Providence, R. I., a graduate of Tufts Medical School, Boston, in 1901, died of apoplexy February 12 at the age of 42 years.

Dr. GUSTAVE A. MUELLER of Pittsburgh, Pa., a graduate of Hahnemann Medical College and Hospital, Chicago, Ill., in 1885, died at his home February 9 at the age of 48 years. He had only recently been appointed a member of the Pennsylvania State Board of Medical Licensure.

Dr. JOHN A. A. HOFFMAN of Champaign, Ill., died on February 16.

Dr. THOMAS C. MINOR died of pneumonia at his home in Cincinnati on February 15 at the age of 65. He was a graduate of the Medical College of Ohio in the class of 1869, and was at one time Health Officer and later Police Commissioner of Cincinnati.

Dr. OSCAR PORZER of Bloomfield, N. J., died in the German Hospital at Newark, while undergoing a surgical operation, on February 20. He was 41 years of age and a graduate of the College of Physicians and Surgeons in Baltimore.

Dr. WILLIAM T. DICKESON, a graduate of the University of Pennsylvania in 1849, died at his home in Media, Pa., on February 21, at the age of eighty-five years.

Dr. KIRBY H. SMITH of Arcadia, Fla., a graduate of the Medical Department of Vanderbilt University, Nashville, Tenn., 1891, died suddenly on February 13 at the age of 50 years.

Dr. HENRY C. GHENT of Belton, Tex., died on February 13. He was born in 1831 and was graduated from Jefferson Medical College, Philadelphia, in 1856. He was at one time president of the Medical Society of the State of Texas and of the Central Texas Medical Association. He was vice-president of the American Medical Association in 1885 and had served as an assistant surgeon in the Confederate Army.

Dr. MINNIE C. ARCHER, a graduate of Franklin Medical College, Philadelphia, in 1894, died at her home in Houston, Texas.

Correspondence.

VACCINE TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record:

Sir:—I have just read with much interest a communication by Dr. H. H. Sinclair, of Walkerton, Ont., entitled "Vaccine Treatment of Pneumonia." The doctor is by no means alone in his experience with the treatment of this disease by bacterial vaccines. As a matter of fact, only three days ago I discharged a patient who had had an evident pneumonia and who had been treated in this manner. This patient, a lady, aged sixty-four years, was a sufferer from chronic interstitial nephritis of fifteen or sixteen years' standing, and naturally I looked forward with much apprehension to the outcome. On the afternon of February 7 I found the patient with a decided consolidation of the upper portion of the left lung, a temperature of 103.4° F., and other evidences of pneumonia, including the pain, malaise, and the other characteristic findings. I was fortunate in securing a specimen of sputum, which on bacteriological examination showed the presence of pneumococcus, streptococcus, and the bacillus of Friedländer, the pneumococci predominating. The same evening I gave the patient 1 c.c. of a vaccine containing 30,000,000 pneumococci, and 20,000,000 streptococci. The next morning the temperature had fallen to 101.1° F., and the expectoration was loose and free, whereas before it was quite difficult to raise. The breathing was free and easy, whereas the day before it had been difficult, painful, and rapid. The pulse had dropped from 96 to 76, and was notably stronger. On the evening of the second day I gave her another dose containing the same number of bacteria and the temperature did not exceed 100° F. after that time. In fact, on the third day the patient considered herself well and wanted to get up. The highest temperature on the fourth day was 98.8° F. Now there is no doubt at all that this was a pure case of pneumonia. The physical signs were absolutely distinct and I was fortunately able to back them up by a careful microscopic examination. The use of a stock vaccine which I was fortunate in having handy made the treatment prompt and effective, and no one was more surprised than I to see the promptness of this recovery in such a supposedly bad subject. In regard to Dr. Sinclair's large doses I have nothing to say. The dosage of bacterial vaccines is by no means established, and as a result, "there is no dose," but dose enough.

Wilbur C. Hamlin, M.D

Chicago, Ill.

To the Editor of the Medical Record:

Sir:—Answering the letter of Dr. Sinclair in your issue of February 10, I would say that in the past four years I have treated twenty-nine cases of pneumonia with bacterial vaccines. There is no doubt at all that the vaccine treatment of pneumonia is as effective as the vaccine treatment of any infectious disease. It is not infallible, that is to say, it is not always a sure cure. Circumstances are met with where the patient is doomed from the start with any kind of treatment. I had such a case. This was a lady of sixty-four, weighing 260 pounds, with fatty degeneration of the heart. She took sick with a double pneumonia, temperature going to 104° F. after the initial chill. A pneumococcus-streptococcus combination vaccine was given at once. The temperature dropped to 100° F. the next day. In all five doses of vaccine were given and the improvement was such by the fourth day that I entertained hopes of her recovery, but by the sixth day she died as a direct consequence of her weak heart. Failure in such a case is no criterion, but even here life was prolonged, showing that the vaccines were of benefit. One patient with double pneumonia whom I saw with another doctor died, in my opinion, because the vaccine was not repeated often enough. This was before we had gotten over the fear of the negative phase in severe acute infections. There was a beautiful response to the first inoculation with a drop of temperature from 104.5° F. to 100° F. in twenty-four hours, with other conditions proportionally improving. The vaccine was not repeated until three days later, after a sharp rise of temperture. This time the response was not so marked, and fearing to repeat the dose, no more vaccine was given. Oxygen, heart stimulants, and supporting treatment were resorted to, but death ensued three days after the second inoculation. From subsequent experience, I am satisfied that if the vaccine had been repeated once or twice after the first inoculation at daily intervals this patient would have lived.

All my other patients recovered. When the vitality and other conditions are reasonably good uniformly good results may be looked for if the vaccine is used early, the earlier the better. I have had four cases where the vaccine was given the first day in which a crisis took place within one day, and two cases in which it occurred within two days after the inoculation. I always used stock vaccines prepared in my laboratory from selected strains procured from typical cases of pneumonia. With stock vaccines treatment can be started at once. The preparation of autogenous vaccines causes too much delay before treatment can be started. In regard to the doses, I think the doctor does not need to give 400,000,000 at one dose, but if he will give the 40,000,000 or even 30,000,000 backed up by a corresponding dose of streptococcus—for it is usual to find the pneumococcus and the streptococcus together in these cases—I think that his results will be even more satisfactory. In my work I have had occasion to come in touch with at least thirty physicians who have treated pneumonia in this manner with equally good results.

There is no doubt in my mind that in the future much will be done with this method of treatment, and my experience has shown that physicians who start the use of vaccine therapy in the treatment of an acute infection such as pneumonia, acute rheumatism, tonsillitis and other similar short infections get results which convert them to this method of treatment and make them confident users of the vaccines in the more chronic and intractable cases.

G. W. Sherman, M.D

Detroit, Mich.

Late Infection of a Laparotomy Scar.—E. Hoke reports the case of a girl aged eighteen years who in the course of an attack of acute rhinitis developed a small abscess in the scar left after an operation for perityphlitis performed three months previously. The abscess opened spontaneously and discharged a small ligature.—*Prager medizinische Wochenschrift.*

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PROBLEMS OF G. P. I.—TREATMENT OF LEPROSY—RECURRENCE OF ADENOIDS—TUNING FORK WITH STETHOSCOPE—INSURANCE; HOSPITALS, COMMITTEES, AND MEETINGS—OBITUARY.

London, February 14, 1912.

THE medicolegal relationships of general paralysis of the insane formed the subject of a discourse by Sir George Savage at the Polyclinic on the 25th ult. His great experience of the disease and the frequent call for his opinion in the law courts lend special interest to the questions that may arise in connection with this disease. Sir George looks for the discovery of some treatment which will arrest if not cure it. If so, it must be in the early stage—the prodromal—which is followed by the acute, and that by a placid stage, passing into the demented one. The dangers are different in each. In the earlier the chief danger was said to be the patient being made the tool of others. Some loss of higher control lets his actions follow feeling rather than reason. The result will vary with the individual—may be seen in anger, violent language, even brutal acts, or by improper companionships, or sexual faults, or acquisitiveness. The degrading tendency of the disease, the seeking low or bad companions must tend to disorder of conduct and sometimes to violent personal attacks. In police cases this should be remembered, for the lecturer mentioned cases in which medical men had diagnosed drink from alteration of speech due to disease. In these cases there is no premeditation, and the attacks are not followed up. Often there is regret and the offer to make amends.

Loss of higher control leads to immorality of various kinds, and hasty marriages which the wives have reason to regret. Assaults on women or children, too, occur. Mostly there is a silly childishness about these acts rather than violence, and they are done openly with no attempt at denial or evasion, contrasting with epilepsy, in which the acts are brutal but are honestly denied, as there is complete loss of consciousness in these. Sir G. Savage summed up this part of his discourse by advising "in any case of assault or indecency in a middle aged man be on the lookout for the physical signs of general paralysis."

The acquisitiveness of the paralytic was explained as a reversion to uncontrolled nature in relation to property. As a child takes what is near and attracts his attention, petty thefts are committed by paralytics. Later on there may be another cause; he comes to think all the world belongs to him or he is so rich he can pay for everything. Such cases were cited; also men writing checks for large sums on banks where they had no account. They would not forge a signature—they believed they had the money. The lecturer knew one man who speculated and actually made a fortune by the time he was in the asylum. How would it have been if he had lost the fortune and the accounts remained unsettled?

Sir George had inquired as to the number of criminal lunatics suffering from general paralysis, and was surprised to find how few they were. In one asylum for criminal lunatics only eight cases in twenty years; in another fifty-eight in fifty years. This may be partly that some have been sent to other asylums or otherwise dealt with for thefts, etc.

Questions of compensation for injury have aroused more importance of late years. The lecturer admitted that though one cause is essential other elements might start the disease. He actually believed meat diet might be a factor, as doubtless alcohol is, and he mentioned that a superintendent had told him that he hardly ever gave meat diet to paralytics, and since he had done this acute phases and epileptiform seizures had disappeared from his asylum.

Testamentary capacity may present more difficulty than might appear at first sight, for our courts have admitted wills made in an asylum. It may be argued the will was made in a lucid interval or he may carry out automatically what he intended in his sane life. Generally the contents of the will influence a jury more than medical opinions.

A Parliamentary white paper was circulated on the 31st ult. containing a further report on the treatment of leprosy at the Mahaica Leprosy Asylum in British Guiana, by Dr. E. P. Minett, assistant government bacteriologist. He finds that nastin has had very little effect on the cases in which it was tried. A solution of benzoyl chloride in petroleum oil shows a somewhat higher percentage of improvement. Anesthetic leprosy runs a definite course, the disease appearing later to die out, and the patient is not then infective. Such cases recover sensation in the previously anesthetic areas and after loss of a part the scar only remains. This is a normal cause without any treatment, and it does not seem to be influenced by either nastin or benzoyl chloride. Nodular leprosy has no tendency to improve naturally except in some very rare instances, nor is it affected by either of the above named drugs. The so-called destruction of bacilli is only a natural process which varies a good deal and is also uninfluenced by these so-called remedies. Dr. Minett considers, therefore, such variation of little value, if any, as an indication of the effect of treatment. On the other hand, the benzoyl chloride in petroleum oil used as a paint on ulcerating surfaces is pronounced to be decidedly valuable, and so it is as a nasal spray. It very soon frees the discharge from bacilli. It is strongly recommended for destroying bacilli in leper asylums.

Recurrence of adenoids is rather rare; some operators have never met with it. Mr. T. Guthrie communicated his experience to the Liverpool Medical Institution on the 25th ult. He finds that age has a great influence in this respect—the younger the child operated on, the more likely a recurrence. Thus it was mostly met with under the age of four years, and might occur in such children although the operation had been as complete as possible. Between the age of four and seven recurrence is less frequent, and after seven Mr. Guthrie admitted that practically it does not occur when the operation has been thorough. He considered it was favored by attacks of specific fevers, syphilis, and by anterior nasal obstruction from bony deformities, etc. He recommended after-treatment of postnasal catarrh and attention to the general health.

At the same meeting Dr. R. J. M. Buchanan demonstrated the use of a tuning fork combined with articulation for the purpose of mapping out the organs of the chest or abdomen, and even determining changes of size or shape. The fork being struck, the stem is placed on the part and moved by degrees while the stethoscope is being used. The sound vibrations vary with the density of the underlying organ, solids from liquids being easily differentiated. So the colon could be distinguished from the stomach and small intestines. Dr.

Buchanan found he could map out consolidated lung and tumor of the mediastinum, and he said in one case he had been able to determine an alteration in the size of the kidney which was shown to be correct on operation.

It is commonly believed that the Insurance Act will have a detrimental effect on hospitals, and it is a fact that many subscribers have given notice of their intentions to withdraw their contributions. It is hoped that they may be induced to reconsider this intention, though some of a socialistic turn commend it as likely to lead to nationalization of our great charities. Germany is so often held up to us as an example that I am glad to report a hospital surgeon's recent examination of Berlin hospitals. He finds their, as some of us knew well enough, a vivid contrast to our own, and has described in *The Times* what he saw on his visit. Mr. McAdam Eccles says the German act works well on the lines it was intended to do. Every insured person has a right of admission to a State hospital—not on account of illness, but as having paid for it. This is in complete contrast with our boast of "supported by voluntary contributions." The State hospitals of Germany are, therefore, administered in a parsimonious way, only bare necessaries (good of their kind) being provided—no flowers, no chairs in the wards, and so on. A more important deficiency noticed by Mr. Eccles was in the nursing staff—a hospital with 600 beds had fifty nurses, in contrast with St. Bartholomew's, about the same number of beds and 344 nurses. The contrast is so great I feel inclined to ask if it is possible that here we may have overdone the staff, especially as at this moment St. Bartholomew's is obliged for the first time in its splendid history to issue an appeal for contributions. Up till now its endowments have sufficed for its maintenance, but the administrators are even whispering that they may have to close some wards; but I do not think the city will let that take place. To return to the statements of Mr. Eccles. He quotes a recent writer to the effect that in the State hospitals gratitude is neither shown nor expected; the service is paid for. Our students, dressers, nurses, and residents are often most gratefully remembered for their attentions, but in Germany the patients would resent it if the students came into such close relationship, for, as von Müller puts it, they have a right to be admitted and "are not at all willing to be examined by the students." You will probably agree with Mr. Eccles that the London system is better for medical education, and one reason why we turn out such humane and reliable as well as highly trained general practitioners. This system is certainly "threatened by the working of the Insurance Act when it comes to affect our large hospitals with their medical schools."

The National Medical Union has passed a vote of censure on the B. M. A. Council and a refusal to accept its report. Further, it has resolved on a renewed pledge refusing to go on any panel or committee until the six points contended for are unreservedly conceded in such manner that they cannot be altered or withdrawn in future except by an act of Parliament. The Union further asks the divisions of the B. M. A. to instruct the Council not to enter into further negotiation with or hold further interviews with the committee or commissioners.

On the other hand, the divisions of the B. M. A. are holding meetings in the different districts to discuss what directions they will give to their delegates to the representative meeting to be held on the 20th. The Council favors the policy of insisting on their six points being conceded under the regulations made by the commissioners. The objectors say that commissions can rescind whatever they agree to.

The Government whips have organized a committee to instruct people about the act by lecturing and other means. They are also responsible for a plan of instructing their lecturers. Some of these have already begun and proved their zeal and ignorance by absurd attacks on the doctors. The Chancellor has had a conference or two with the commissioners and others, and it is said he begins to see that, after all, these doctors are in earnest; they even laugh at his threat to appoint whole time men to attend the "ten million or so he has swept into the insurance net."

The large Friendly Societies have decided to become "approved societies" under the act.

This morning a circular signed by fifty practitioners has been issued advocating "a strong but moderate policy." They seem to fear that the Chancellor will meet the strong policy by suspending the medical benefit and giving the insured the equivalent in cash, in which case they believe the approved societies would step in and reorganize contract practice on the old club lines. But they forget that for the first time the profession seems united and could therefore decline the clubs. This appeal and one or two others all advocate sticking to the six points and working in conjunction with the B. M. A.

Brigade Surgeon Henry Elmsley Busteed, late of the Indian Army and assay master of the Calcutta mint, died on February 1 in London, in his 80th year. He obtained his first commission in the Indian Medical Service in 1855 and retired in 1886, when he was made C.I.E. During his service he was in the mutiny campaign, taking part in the relief of Lucknow and being awarded the medal and clasp. In 1861 he was civil surgeon at Cuddalore and in 1865 was appointed assistant assay master, and subsequently master of the mints successively at Madras, Bombay, and Calcutta. He was also Commissioner of Paper Currency. He was author of "Echoes from Old Calcutta."

Dr. David Christison of Edinburgh died on January 21, in his 83d year. He was the second son of Sir Robert Christison, his elder brother, Alexander, being the present baronet and a retired surgeon-general. He took his M.D., Ed., in 1851, and became F.R.C.P., Ed., in 1862. Six years ago he had the LL.D. conferred upon him. He went to the Crimea in the early part of the expedition. He was a naturalist of authority as well as a physician, and for many years secretary of the Scottish Society of Antiquaries. To this and other scientific societies he made many valuable contributions and wrote two or three volumes on the antiquities of Scotland.

OUR LETTER FROM THE PHILIPPINES.

MANILA MEDICAL SOCIETY—INFANTILE BERIBERI—BLONDS AND BRUNETTES IN THE TROPICS—ELECTION OF OFFICERS.

MANILA, P. I., January 9, 1912.

THE regular monthly meeting of the Manila Medical Society was held on the roof of the College of Medicine and Surgery, University of the Philip-

pines, at 8.30 P.M. An unusually interesting series of papers was presented, the first being entitled, "As to Infantile Beriberi. A Preliminary Report," by Dr. Vernon L. Andrews. The work done by Dr. Andrews was largely a continuation of the study of beriberi presented in a previous paper by Drs. McLaughlin and Andrews at the first meeting of the Far Eastern Association of Tropical Medicine, in March, 1910. In this paper, however, Dr. Andrews reported that, in addition to making the diagnosis by autopsy, in a large number of instances he was able to see the cases before death and make a satisfactory clinical diagnosis, which was confirmed, in almost every instance, by his autopsy. The importance of this matter will be appreciated when it is remembered that a number of local physicians still doubt that such a disease entity as infantile beriberi exists. In practically every instance in which the child died of beriberi, its mother showed many symptoms of the disease. Dr. Andrews gave a large series of analyses of milk taken from mothers whose children had died of beriberi. These showed, among other things, that the percentage of phosphorus pentoxide (P_2O_5) was, in most instances, as great as in normal milk. This point is of importance in view of the fact that beriberi has been attributed to the lack of phosphorus in rice. The sugar was about normal; the proteids were slightly below normal. A more striking difference occurred in the fats. With one exception they were approximately 50 per cent. under the normal amount. Dr. Andrews induced a number of mothers who had symptoms of beriberi to nurse puppies, and while he has not yet a sufficiently large amount of data from which conclusive deductions could be drawn, still, in one instance, one of the nursing puppies contracted a typical case of polyneuritis. Dr. Andrews' autopsy diagnosis was beriberi.

The next paper, entitled "The Cure of Infantile Beriberi by the Administration to the Infant of an Extract of Rice Polishings, and the Bearing Thereof on the Etiology of Beriberi," by Major W. P. Chamberlain and Captain E. B. Vedder, United States Army Medical Corps, was read by Dr. Vedder. The results shown in this paper mark a distinct advance in the treatment of the condition locally known as taon, or infantile beriberi. The statistics of the Bureau of Health show that 50 per cent. of all infants born in Manila die before they reach the age of one year, and that a large percentage of the deaths are attributable to this condition. In view of the previous high mortality, the results obtained in the fifteen cases which Dr. Vedder reported were truly startling. The diagnosis in each case was concurred in by at least three independent physicians, so that the diagnostic error was eliminated as far as possible. Dr. Vedder stated that upon the administration of the extract of rice polishings the child usually showed improvement within a few hours. The child usually slept well the first night after treatment. The beriberi symptoms cleared up in the course of a few weeks, with the exception of the aphonia, which persisted generally for two months or more. This he attributed to the fact that the degenerative changes in the pneumogastric nerve were so extensive that at least this period of time was required before a sufficient degree of nerve repair could take place. The extract is made by taking 3 liters of 92 per cent. alcohol and mixing it with 1 kilogram of rice polishings and allowing it to macerate for a period of forty-eight hours. At the end of this time the alcohol is evaporated slowly, over a water bath, at a temperature which must not exceed 80° C. Considerable stress is laid upon the fact of not permitting the temperature to reach the boiling point, because there is great danger of the active principle being destroyed thereby. Water is then added to the residue and the precipitate is filtered and sufficient water added so that each cubic centimeter represents 60 grams of the rice polishings. In the discussion which followed, Dr. Heiser called attention to the fact that while beriberi had disappeared almost entirely among persons who were employed at lighthouses, among inmates of jails, insane hospitals, and other persons who were under Governmental control, yet, judging from the statistics of the city of Manila, there had been a decided increase in the number of deaths from beriberi. He said that this might, in part, be accounted for by the increased attention which has been directed toward beriberi in the past few years, and cases which had heretofore been overlooked were probably now being reported as beriberi, but, in spite of this, when one considered that the beriberi deaths in the city of Manila had increased from approximately 700 in 1907 to 1500 per annum in 1911, further reasons had to be sought for to explain this. He thought that if the knowledge that beriberi in infants could be readily cured could be made general, and the treatment supplied gratis, there was considerable hope that a marked reduction in the infant mortality would be brought about. It was, of course, understood, he said, that the primary object to be sought was to prevent beriberi in the adult, and the best hope of accomplishing this lay in the bringing about of a more general use of undermilled rice.

Dr. Richard P. Strong said that he wanted to take exception to the statement that polyneuritis gallinarum and beriberi were the same condition. He stated that it might possibly be the case, but there was yet insufficient evidence on hand to make this statement conclusive. He called attention to the fact that so far it had been impossible to produce beriberi in monkeys and guinea pigs.

Dr. Vedder, who replied, stated that it was very difficult to induce dogs and guinea pigs to eat rice. In some instances these animals preferred to starve rather than to touch it. He called attention to the experiments of Shiga, which were published in the May number of the *Archiv für Schifs und Tropen Hygiene*, in which Shiga stated that he had been able to produce beriberi in a guinea pig, and gave a report of the pathological findings.

The next paper, entitled "The Relative Resistance of Blonds and Brunettes to the Harmful Influences of a Tropical Climate," was presented by Major Weston P. Chamberlain, United States Army Medical Corps. Dr. Chamberlain gave the observations made, in some instances, on a thousand troops, which consisted in noting the resistance to disease as shown by the sick admission rate of the various hospitals. The general behavior, as shown by court-martial trials, was recorded because Major Woodruff stated in a paper that, owing to the irritating effect of the actinic ray on the lighter skinned races, they became more irritable and were inclined to commit various kinds of misdemeanors. Their habits as to sobriety were also compared. Comparisons were made as to the incidence of insanity among them, and various other tests. In all of these there was practically

no difference in the two types, when large numbers were dealt with, and in some instances the brunettes were at a disadvantage in the comparison.

The society elected officers for the ensuing year: *President*, Major Percy M. Ashburn, Chairman of the United States Army Board for the Study of Tropical Diseases; *Vice-President*, Dr. R. E. L. Newberne; *Editor* of the society's journal, Dr. W. E. Musgrave; *Secretary and Assistant Editor*, Dr. A. G. Sison. The positions of *Treasurer* and *Business Manager* and *Counselor* were laid over for action at a subsequent meeting.

A Study of the Different Approaches to the Hip-Joint, with Special Reference to the Operations for Curved Trochanteric Osteotomy and for Arthrodesis. E. G. Brackett.
Prevention of Infant Mortality by Breast Feeding. W. H. Davis.
Liver Cyst, a Rare Case (with a Moral). F. J. Cotton and A. M. Burgess.
Three Unusual Cases: 1, Cyst of the Liver; 2, Volvulus and Strangulated Internal Concealed Hernia Complicating Pregnancy; 3, Acute Torsion of Hydrosalpinix Complicating Pregnancy. R. M. Green.

Operative Approaches to the Hip-Joint.—E. G. Brackett notes that the special problems presented by this joint are dependent on the following facts: it is the deepest joint in the body; it is covered on all sides by more than one layer of muscles, the edges of which so overlap as to prevent any direct entrance without either section or very marked retraction; and it is not possible to expose more than a limited area in the neighborhood of the hip-joint without serious damage to its essential coverings, and even when an avenue of approach to the joint is clearly opened, the joint itself is still hidden and cannot be opened without damage to its intrinsic articular structures. The most practical of the routes of approach are the following: the inner, anterior, lateral, latero-posterior, and posterior routes. Each of these is described in detail.

Prevention of Infant Mortality.—W. H. Davis presents the result of a study undertaken with the object of determining the relationship between breast-feeding and the prevention of infant mortality. Letters were sent to 900 mothers who had births recorded in Boston during the previous year. Of 736 replies, 533, or 72.4 per cent., of the infants were breast-fed and 27.6 per cent. were bottle-fed. As regards the nationality of the mother, Italy leads with 83 per cent. breast-fed; Russia and Poland come next with 79 per cent. breast-fed; Ireland and the United States follow with 73 per cent. and 59 per cent., respectively; while Canada makes the poorest showing with only 51 per cent. breast-fed. There is only a slight increase of deaths among breast-fed babies during the summer months. Only 26 per cent. of infant deaths between the ages of two weeks and one year occur among breast-fed babies. And of infants over two weeks old, born of native mothers, only 16 per cent. of the deaths occur among breast-fed children; while of babies over two weeks of Italian mothers 53 per cent. of the deaths occur among breast-fed children. Bottle-fed babies between the ages of one and three months show the highest mortality, especially those babies having mothers born in the United States. The bottle-fed infant over two weeks old is six times as likely to die as the breast-fed infant. Breast-feeding of all babies would have saved in one year in the city of Boston nearly a thousand lives.

Liver Cysts.—F. J. Cotton and S. M. Burgess note the extreme rarity of liver cysts, and that many cases of so-called malignant disease of hopeless type prove, in fact, to be conditions readily relievable by simple surgical measures. They report a case of liver cyst occurring in a woman aged 60. She had all the evidences of malignant disease: loss of weight, cachexia, and the presence of an epigastric tumor. On exploratory operation there was discovered near the middle of the left lobe of the liver a smooth bluish domed mass about three inches in diameter. This mass was tapped and yielded a colorless fluid under high pressure. The cyst was emptied and drained and the patient made an uninterrupted recovery.

Unusual Cases.—R. M. Green reports a case of hepatic cyst in a colored woman aged 50 in which the clinical picture simulated that of a subserous fibroid with a twisted pedicle. He also reports a case of volvulus and strangulated internal concealed hernia complicating pregnancy in a woman aged 27. The condition in this case was apparently a congenital anomaly of the mesentery, with high position of the cecum, leaving a tent-shaped cavity, into which the small intestines passed, forming an internal concealed hernia, which, becoming strangulated during pregnancy, caused an acute abdominal emergency. A third case reported is that of a hydrosalpinx complicating pregnancy in a patient aged 26. This case presented the somewhat rare condition of spontaneous torsion of a presumably pre-existent hydrosalpinx complicating pregnancy and producing a train of symptoms exactly simulating those of acute, intercurrent appendicitis.

Indiscriminate Drug Taking. A. Lambert.
Some Useful Household Medicaments. S. Solis-Cohen.
Masturbation in the Adult Male. M. Hühner.
Crile's Researches in Regard to Shock. W. P. Carr.
Local Anesthesia in Major Surgery. S. Morrow.
The Matas Operation in the Treatment of Traumatic Aneurysm. W. C. G. Kirchner.
Artificial Sterilization by Active Immunity with Spermatozoon from the Same Species. L. K. Hirshberg.
Chronic Urethral Pruritus. G. Greenberg.
Acute Poliomyelitis with Unusual Manifestations. M. Greenwald.
Interstitial Ectopic Gestation. C. R. Rohins.

Indiscriminate Drug Taking.—A. Lambert states that the dangers of indiscriminate drugging may be summed up as follows: It is often harmful and usually unintelligently useless. The drugs in themselves frequently do harm, to say nothing of the waste involved in pouring in enormous quantities of these remedies to no purpose, since the reasons for which they are taken are often incorrect. Many of these remedies do harm in that they actually injure and pervert the normal processes of the body. It is like the old Persian proverb concerning opium, which runs, that while opium may cure a disease it also produces one. All narcotic drugs, those which benumb pain and the like, have the danger of real habit formation connected with their use and when once a person is addicted to these drugs, the condition in which he finds himself is worse than the previous one for which they were taken. It is an old, trite saying of the medical profession that he who diagnosticates well will cure well, and this applies to each and every individual, whether he has taken a degree in medicine or whether he has not, and certainly the indiscriminate drugging to which the human race is to so great an extent addicted today is not based on principles of good sense and intelligence.

Household Medicaments.—S. Solis-Cohen notes the value of castor oil, which may be left in the hands of the mother without fear, and which may be administered at the beginning of most fevers or of so-called "colds," in cases of acute indigestion, in cases of ptomaine poisoning, in certain kinds of acute diarrhea, and the like. An effective household remedy is a mixture of equal parts of castor oil and spiced syrup of rhubarb. At the beginning of attacks of "colds" moderate doses of quinine are useful. Tincture of iodine is a good old household friend. Compound tincture of benzoin is useful for chapped hands, slight cuts, and bruises of various kinds. Senna and rhubarb are safe household purgatives. Other

Household remedies that have demonstrated their usefulness are spirits of camphor and aromatic spirits of ammonia.

Masturbation in the Adult Male.—M. Huhner concludes that masturbation is a real disease, causing real discomforts, and is not an imaginary condition. One should not blame every symptom the patient complains of on his masturbation, as these symptoms may be due to pathological conditions in other organs. Masturbation and pollutions are distinct conditions, although they may coexist. Masturbation is dependent upon a pathological condition of the prostatic urethra and not upon imagination on the part of the patient. Coitus will not cure masturbation and is a dangerous experiment. Masturbation is to be treated by removing the pathological condition in the prostatic urethra and not by punishment or talking it out of the patient or appealing to his self-control. Masturbation is a curable condition. The treatment consists of the following measures: prostatic massage and deep urethral instillations of a 1 to 3,000 solution of silver nitrate by means of a Bangs sound syringe. At first a small sound syringe is used; as the case progresses larger sizes are employed and at the same time the strength of the silver solution is gradually increased until a strength of 1 to 500 is reached. Treatments are carried out every five days, and the entire course of treatment takes five months.

Crile's Researches on Shock.—By W. P. Carr. (See MEDICAL RECORD, January 10, 1912, page 142.)

Local Anesthesia in Major Surgery.—A. S. Morrow concludes that local anesthesia has a field of usefulness far greater than is generally recognized at the present time and that nearly 50 per cent. of the operations now performed under general narcosis could be just as successfully done under local means, intelligently used. The author believes that we have become accustomed to depend too largely upon general anesthesia. While it is true in the average case in good condition, the dangers from a general anesthetic in the hands of a skilled anesthetist and competent operator are very small; yet it must be remembered that under similar conditions local anesthesia, producing less shock, no kidney, heart, or lung complications, no blood changes and no gastric disturbance, is still safer; and if an operation can be satisfactorily and thoroughly performed under local means then local anesthesia should be offered to the patient, if for no other reason, simply to avoid the well-known unpleasant after effects of general narcosis, regardless of whether the particular operation is classed as a major or minor one.

The Matas Operation for Traumatic Aneurysm.—By W. C. G. Kirchner. (See MEDICAL RECORD, January 27, 1912, page 141.)

Artificial Sterilization by Means of Injections of Spermatozoa.—L. K. Hirshberg sought to determine whether it were possible to create sterility by inoculating the female of a species with whole spermatic fluid from the male of the same group. The result was negative. The author states that this might be put paradoxically in a burlesque way by stating that the Mendelian law is again substantiated in these cases; for acquired sterility cannot be either produced or "thereby transmitted to the offspring."

Chronic Urethral Pruritus.—G. Greenberg notes that this is due to either local or constitutional causes. Of the former, urethral polypi are the most frequent. Other local causes are strictures, chronic posterior urethritis, prostatitis, and seminal vesiculitis, and the presence of abnormal constituents in the urine. The constitutional causes are rheumatism, gout, neurasthenia, gastrointestinal disturbances, masturbation, alcoholism, and drug habits. The treatment consists in removal of the cause, constitutional treatment, and in intractable cases the use of an ointment consisting of ichthyol, one dram; resorcin, ten grains; quinine and urea hydrochloride, one-half dram, and lanoline, two ounces. This is applied to the urethra by means of an ointment sound.

Poliomyelitis.—M. Greenwald reports a case of this condition.

Interstitial Pregnancy.—C. E. Robins reports a case of this condition, presenting the unusual feature that no bleeding occurred at any time.

Journal of the American Medical Association.

February 17, 1912

Diphtheria and Vivisection.—W. H. Park recites the history of modern progress in the treatment and knowledge of diphtheria, showing how the identity of membranous croup and laryngeal diphtheria has been recognized and the methods by which the discovery of the diphtheria bacillus and the acquisition of a remedy have been obtained. Statistics show that the deaths from diphtheria per 100,000 population have been reduced from over 200 in 1887 to 37 in 1910. In the London Hospital the mortality has been reduced from about 30 per cent. in the early nineties to less than 10 per cent. In the pre-antitoxin years, while there were fluctuations in the mortality, in no period did all the cities show even a slight decrease, but it is only when we come to the critical year, 1894, that the drop in the mortality, which has progessively continued to the present time, began.

Cancer of the Breast.—W. S. Thorne emphasizes the fact that in a certain percentage of cases tumors of the breast dignosed as malignant do not undergo malignant degeneration and that the histological arrangement of a tumor does not always necessarily determine its future life history or development. The author suggests that possibly a certain proportion of recoveries should be credited to the natural defenses of the body. The usual three years' period of recovery he considers a mistake, and he shows cases illustrating the vagaries in development and appearance of tumors diagnosed as malignant. One of these disappeared without treatment, but recurred afterward in other parts of the body after a long lapse of time. The consensus of medical opinion is that 85 per cent. of breast tumors are malignant and the radical operation is in vogue, though not always justified by the pathological findings. The radical operation is mandatory without exception, but disfiguring operations should be avoided unless unequivocally necessary.

Salt Restriction.—A. C. Croftan finds that simple salt retention does not explain all cases of edema and certain toxic factors no doubt take a part. But whenever nephritic edema is due to salt retention, restriction of the intake is rational, much more so than endeavoring to force a sick kidney into action by drugs. A certain amount of the retained salt becomes attached to the cell protoplasm (*chlorure fixé*) and this is much more slowly gotten rid

of than that which remains free in the kidneys, an addition of a small amount of salt in the diet will cause the reappearance of edema, as the cell capacity is already overtaxed. It is somewhat difficult to explain the increased excretion of chlorides following reduction of the salt intake, but the author suggests that the kidney may be rested and thus better able to do its work. Occasionally there may be an increase of edema with excessive reduction of salts due to insufficiency of the kidneys to automatically dilute and concentrate the urine. Another factor which reduces edemas when salt is restricted is the greater facility of water evaporation from the lungs and skin when the body fluids are less concentrated. Prior to chloride restriction a tolerance test for salt should be made, the chloride content of the body determined, and the urine tested on several successive days. In very acute forms of nephritic edema restriction of drink is valuable with the salt restriction and the latter should be persisted in over a considerable time. The process of salt elimination can be occasionally started by the judicious use of diuretics, though, as a rule, they can be very well dispensed with. The resumption of sodium-chloride feeding should be very gradual, even after the disappearance of the edema. Chloride restriction has other fields of usefulness, such as epilepsy, diabetes insipidus, certain cardiac conditions and obesity. It sometimes helps in diabetes, though not always. It at all events helps reduce the thirst and is worth trying. It is of the greatest value in the treatment of inflammatory serous exudates, in certain stages of croupous pneumonia and whenever it is desired to produce a bromide effect. It can also be considered an antidote against bromidism. It is, however, by no means a panacea for all nephritic edemas. With careful selection of types, however, and with methodical restriction and control salt restriction can probably never do harm and will usually do good. If employed as a routine measure without control in every case, it will more often disappoint than fulfill expectations.

Anesthesia.—J. C. Gwathmey discusses the merits of different methods of anesthesia.

Foreign Bodies in Air Passages.—E. F. Ingalls reports three cases of bronchoscopy for the removal of a tack or nail in the air passages.

Repair of Facial Defect.—R. C. Turck reports a case of extensive facial defect successfully operated upon.

Scalp Tourniquet.—E. Laplace recommends in the treatment of hemorrhage from scalp wounds the application of four turns of a quarter-inch rubber tubing around the head at the level of the external auditory meatus.

Fractures in the Base of the Skull.—R. L. Payne advocates the decompression operation as the only correct treatment for basal fractures of the skull, as indicated by the experimental results of Hill, Cushing, and Krause. Heretofore the treatment had been irregular and the mortality 64 per cent. up to within the last five years. He reports a case treated by decompression with remarkably good effects closely following.

Cerebral Hemangioperithelioma.—W. G. Spiller gives the history of a case of multiple perithelioma of the brain attended with hemorrhages which is unique in his experience, and he has not found a similar one in the literature. The tumors were very numerous in this case, and every tumor was the site of hemorrhage. They varied greatly in size, the largest measuring 2 by 3.5 cm., and some were the size of a pea or less. The case illustrates the malignancy that perithelioma may assume in the brain, as the tumors were found in the cerebellum and pons, as well as in the cerebrum. Ordinarily, endotheliomas of the brain are among the most benign of brain tumors, arising from the dura and causing atrophy of the underlying brain by pressure without infiltration. In this case most of the tumors had connection with the cortex, but some were subcortical. The patient, a man, aged 69, was suddenly taken with aphasia and paralysis about a year before coming under the author's care, and he more recently had convulsions of the Jacksonian type. He died after an attack of these.

Prolonged Anuria.—V. D. Dunn reports a case of anuria of 114 hours' duration in a middle-aged man suffering from acute edema of the kidney of unknown cause. The operation of decapsulation was performed with complete success.

Twin Ectopic Pregnancy.—E. O'N. Kane reports a case of twin ectopic gestation which had been treated for indigestion and suspected miscarriage. The abdomen was filled with blood, fluid, and clots, and a large adherent mass in the lower abdomen contained a large sac in which lay two fetuses, the cords of which lay close together, rising from a large single placenta.

Ether Valve.—D. E. Jackson describes a new form of ether valve for experimental work which he claims saves more than half the amount of ether ordinarily used.

Antibodies Produced by Tissues Living Outside of the Organism.—A. Carrel and R. Ingebrigtsen find that guinea pig's bone marrow and lymph gland cultivated for five days with goat's blood generate substances that are hemolytic for goat's red blood-corpuscles. The authors conclude that tissues living outside of the organism react against an antigen by the production of an antibody.

Hemorrhagic Disease.—F. R. Frazier reports a case of hemorrhagic disease in an infant aged 10 months successfully treated by direct transfusion of blood from the father.

Early Nerve Involvement in Syphilis.—J. G. Hackness reports a case in which manifestations of syphilis of the nervous system appeared five months after the initial lesion.

Removal of Paraffin from the Bladder.—S. D. Van Meter reports a case in which benzine was successfully used to dissolve a mass of paraffin that had slipped into the bladder from the urethra into which it had been introduced in the form of a bougie.

Certain Chronic Glandular Enlargements. W. K. Hunter.
Amputation for Diabetic Gangrene. C. B. Lockwood.
The Treatment of Puerperal Septicemia by Bacterial Vaccines. G. T. Western.
The Vaccine Treatment of Simple Goiter. R. McCarrison.
The Fate of the Appendix After Abscess Formation. A. P. Dodds Parker.
A Case of Tuberculosis with Special Involvement of the Heart. P. Bahr.

Chronic Glandular Enlargements.—W. K. Hunter distinguishes two groups of chronic glandular enlargements. In the first the outstanding morbid change is a marked hyperplasia of the lymphoid cells. These cases are included under the term lymphocytoma, which comprises cases of pseudoleucemia, the lymphatic leucemias, and the lymphosarcomata, as well as any glandular enlargement due to an overgrowth of the lymphoid elements in the gland. In the second group of cases the enlargement depends on an overgrowth in the connective tissue elements in the gland. The most striking example in this group is that seen in Hodgkin's disease. There are cases of tuberculous or of syphilitic adenitis, which clinically are very difficult to differentiate from Hodgkin's disease, and the same applies to certain chronic inflammations of glands, infective in origin, but not necessarily always due to any one specific bacterium. This last type of enlargement may be called chronic simple adenitis. A third group includes tumor growths.

Amputation for Diabetic Gangrene.—C. B. Lockwood notes the high mortality of amputation for diabetic gangrene and states that death following amputation is brought about either by septic infection or diabetic coma.

Vaccines in Puerperal Sepsis.—G. T. Western has found that the mortality among those cases of puerperal septicemia in which there is definite bacteriological evidence of bacteria in the blood stream is from 85 to 90 per cent. This mortality may by inoculation with autogenous vaccines be reduced to about 55 per cent. The mortality among notified cases of puerperal fever is about 60 per cent. This mortality may by inoculation with appropriate vaccines be reduced to about 30 per cent. In cases of puerperal sepsis if it is decided to explore the uterine cavity the opportunity should not be lost of obtaining a culture at the same time. In the treatment of puerperal sepsis "stock" vaccines give inferior results, and should be used only when an autogenous vaccine cannot be obtained.

Vaccine Treatment of Goiter.—R. McCarrison reports favorable results from this method of treatment. The vaccines employed were prepared from organisms similar to the normal and harmful inhabitants of the intestines. There is at present no evidence that any one of these possesses a specific influence in the production of goiter. The conclusion is suggested that the thyroid gland is called upon to combat several poisons normally present in the human intestine. When to these is superadded the specific virus of goiter an abnormal element is introduced and an extra strain is thrown upon the gland. Unassisted, it undergoes hypertrophy in many cases, but if assisted in any one direction it is capable of performing the additional task which has been imposed upon it and of combating the abnormal virus. On the assumption that no one of the different vaccines which the author has employed contains the specific organism of goiter the author's explanation of their action in this disease would be that they cause the disappearance of the goiter by relieving the thyroid of part of its normal work, thus enabling it, without continuing in a state of hypertrophy, to destroy the specific toxin of goiter.

Fate of Appendix After Abscess Formation.—A. P. Dodds-Parker states that in this condition the appendix is never destroyed but is damaged. There is a decided liability to fresh attacks. In the present keen struggle for existence it is wiser to remove such a menace to life. The danger of a second operation is not great, and herniæ may at the same time be cured.

Tuberculosis of the Heart.—P. Bahr and G. C. Low report a case which furnishes an excellent example of a tuberculous myocarditis and with such advanced caseous masses replacing almost entirely the whole muscular substance of the heart it is extraordinary how life could have been prolonged as long as it was. The caseation and cheese-like masses were quite typical of tubercle.

Prognosis. T. F. Gardner.
The Early Diagnosis of Pulmonary Tuberculosis. F. W. Price.
The Influence of Strong, Prevalent, Rain-bearing Winds on the Course of Phthisis. W. Gordon.
An Address on the Prevention and Treatment of Pulmonary Tuberculosis. W. M. Crofton.
Notes on Clinical Trials with Marmorek's Antituberculosis Serum. J. P. Mitchell.
As to the Nature of the Parasites of Leprosy and Tuberculosis. A. G. R. Foulerton.
A Case of Actinomycosis of the Lung. F. Nicholson.

Prognosis.—T. F. Gardner points out the power for good or ill which the utterance of a favorable or unfavorable prognosis has on the patient. In doubtful cases physicians should hesitate to predict how long the patient will live. A hopeful prognosis has a distinct therapeutic value.

Early Diagnosis of Pulmonary Tuberculosis.—T. W. Price discusses the symptoms and physical signs that are important in making an early diagnosis of pulmonary tuberculosis.

Strong Rain-Bearing Winds and Tuberculosis.—W. Gordon notes that exposure to strong, prevalent, rain-bearing winds tends to exercise an unfavorable influence on the course of phthisis.

Pulmonary Tuberculosis.—W. M. Crofton states that the methods of combating this disease are broadly three in number: (1) the open-air treatment in hospitals and sanatoria; (2) therapeutic immunization with one or other of the tuberculins; (3) the exhibition of drugs for bactericidal purposes. Many drugs have been used in the disease, such as creosote, guaiacum, carbolic acid, formalin, etc. The one the author prefers is iodine given in chemical combination. The form which he has been using for several years is iodoform, and he has given it intravenously, intramuscularly, and by the mouth. The intravenous method is by far the most potent. It is given in quantities of ¼ to 1 grain dissolved in ether with a little liquid paraffin added two to five times a week. The veins usually selected are those of the antecubital fossa.

Marmorek's Antituberculosis Serum.—J. P. Mitchell reports good results with this remedy in ten cases in which he has employed it. Two methods of injection are used—hypodermic and rectal. The former is supposed to be beneficial in acute and rapidly advancing cases, while the latter is more efficacious in chronic and apyretic cases. The great drawback to the subcutaneous injection is supersensitiveness, which is common to the injection of all serums. The dose used was 2½ c.cm., given hypodermically, until anaphylaxis was seen, when 5 c.cm. were given rectally daily for fourteen to twenty-one days. This was followed by an interval of seven to ten days without serum, which was again followed by daily injections for fourteen to twenty-one days. This routine was carried on as long as the case demanded it. Marmorek recommends that even after recovery seems complete weekly doses of 5 c.cm. should be given for several months. There is no danger in administration apart from anaphylaxis, which can be overcome by adopting the rectal method. In certain cases the general improvement is most striking, although physical signs are not altered to a similar extent. The success obtained in some of the cases at any rate justifies further clinical trials.

The Parasites of Leprosy and Tuberculosis.—H. G. R. Foulerton suggests that the acid-fast forms of Streptothrix may represent not only persistent but also specially resistant elements. The spherical spores of the streptotricheæ are generally distinctly less resistant against injurious physical and chemical influences than are the spores of fission fungi; and it may be that a second resistant element—the acid-fast rod form—has come into existence. Thus Marino found that the acid-fast forms of the parasite of tuberculosis preserved their vitality for a considerable time in the intestinal canal of the leech, resisting the action of the digestive juices for as long as fifteen months. At the end of that time there was marked attenuation of virulence; but still inoculation of the parasites into the guinea pig was followed in some cases by a very slow infection which resulted in death. There is also evidence of a probably similar kind with regard to the parasite of leprosy. It has been suggested that growth of this organism on artificial media is favored in symbiosis with intestinal amebæ, and Williams has recorded his own experiments bearing on this question. With certain strains of his streptothrix the acid-fast-forms appeared to die out in the course of successive subcultures. Then subcultures which appeared to consist of non-acid fast diphtheroid rod segments were mixed with amebæ. At the end of forty-eight hours the amebæ were found to be full of acid-fast rod segments. But an explanation other than that which supposes favorable symbiotic influences may be suggested. There is evidence that bacteria form a part of the natural food of the intestinal

amebæ, and of *Ameba dysenteriæ* in particular. And under the circumstances it would seem most likely that the amebæ digest and assimilate the non-acid-fast segments of the streptothrix, and that in the struggle for prolonged existence other, more resistant, acid-fast forms survive, as Marino's experiments have shown to be the case with the acid-fast form of the parasite of tuberculosis which is resistant against the digestive ferments of the leech.

Actinomycosis of the Lung.—F. Nicholson reports a case of this condition.

Berliner klinische Wochenschrift.

January 29, 1912.

The Berlin Wholesale Poisoning.—Stadelmann states that the first impression made on him by the patients was that of botulism, but there were no motor palsies. In every other respect the affections seemed identical. It was, however, inconceivable that sausage poisoning could occur with male victims only, for women of the class attacked eat freely of smoked foods. As soon as it became rumored that poisonous spirits had been sold at a certain dram shop methylism was suspected. No one knows just how the rumor started, but it is believed that some of the public reported it to the police. The author personally was informed by men in the drug trade. It is grave error to believe that methylism is easily recognized from its symptoms. Pure wood spirit may be almost free from special odor or taste, and it is doubtful if many could distinguish between it and alcohol. Some of the victims died before any characteristic symptoms could develop, for, unlike alcohol, the more deadly methyl spirit does not rapidly intoxicate, some 24 to 36 hours being necessary for the development of its syndrome. It is not burned in the body to CO_2 and water, like ethyl alcohol, but is but little decomposed and slowly eliminated. Its effects are distinctly cumulative, so that while one dose may cause no ill effects, a daily repetition would soon manifest itself by a sudden explosion. A single dose of it large enough will immediately produce symptoms. The retailer got the poisoned spirits in and first sold it on December 23, and the first victims were seen on the 26th, while there were no new victims after the 31st.

Etiology of Diabetes.—Hirschfeld, as the result of a study of this subject based on some relatively new viewpoints, concludes that arteriosclerosis, together with two affections commonly supposed to stand in causal relation with it, viz., alcoholism and syphilis, has been shown to stand in no necessary causal relationship to the development of the pancreatitis, upon which diabetes so frequently depends. An entire series of facts, on the other hand, goes to show that the latter is due to bacteria or bacteriotoxins. Animal experiment, as well as chemical experience, points in this direction. It is believed, for example, that pancreatitis sometimes accompanies mumps. We know that after certain affections, such as angina and influenza, diabetes becomes aggravated; so that we may imagine an acute exacerbation of an old pancreatitis. In some cases diabetes may be attended with enlargement of the liver, which suggests that this organ and the pancreas may be involved in the same process. When these patients begin to improve under an antidiabetic regimen the swelling of the liver subsides.

Angina and Enlarged Liver.—Bortz describes what he believes to be a unique case, which occurred in the nine-year-old son of a diabetic mother, who developed an angina with deposit and high temperature. By mere chance it was found that the liver was notably enlarged. In three days the throat was well and the boy back in school. The liver resumed its normal dimensions. Glycosuria did not develop at any time. The chief interest in the case lay in the fact that, as the boy came from a diabetic family, the liver swelling might have indicated some peculiar susceptibility of that organ to general infections. The pancreas could have similarly participated (evidently it did not), and should the boy later develop diabetes the liver swelling could be regarded as a prodrome.

Deutsche medizinische Wochenschrift.

February 8, 1912.

Cirrhosis of the Liver.—Baumler sums up his lecture on this subject as follows: Cirrhosis of the liver is to be comprehended chiefly as the terminal stadium of some chronic intoxication (such as alcoholism) or as the effect of an acute or chronic infectious disease, or, finally, as a result of chronic biliary or cardiac stagnation. The picture of cirrhosis may also come about secondarily through disease processes of adjacent organs, for example, in peritonitis, especially the tuberculous form, pylephlebitis, etc. Whatever its origin, cirrhosis must always be managed by dietetics and regulation of the intestinal activities. Ascites requires, first, diuretics, then puncture, and, as a last resort, Talma's operation, which, however, must be done seasonably. If biliary stasis is present the treatment becomes that of cholelithiasis.

Origin of Carcinoma from Scar Tissue, etc.—Theilhaber states that without some antecedent atrophy of the parent tissues there can be no cancer or at least only a small proportion of cancers. The most frequent cause of atrophy is the presence of old scars, from prolonged inflammatory changes, or destruction of soft parts as a result of traumatism (including those incident to parturition); in the same category belongs the climacteric atrophy of the uterus and breasts and senile atrophy. From this point of view the surgery which removes cancer also paves the way for scar relapses, and the more extensive the operation the greater the scar area, and hence the greater the predisposition to more cancer. In a word, a large number of recurrences are not really such, but are new primary growths, and there can be no true probationary period after operation.

Parasitism and Disease.—Theobald Smith of Harvard has recently lectured at Berlin on the part played by animal plagues in human disease and in evolution in general. Without the supposition of great animal plagues in prehuman ages it is very difficult to explain the disappearance of many animal species. A widespread rat pestilence may have been the essential cause of the medieval black death, and a study of the epidemiology of all the domestic and familiar animals is necessary for the protection of posterity, since we depend upon some of the species for much of our food and clothing. Should a pestilence spring up which would annihilate cattle or sheep, for example, the sufferings of the next generations would be inconceivable. What is true of the animal world also holds good for the diseases or parasitism, of the uncivilized dwellers of the tropics. The law of Nature that the strong destroy the weak or compel them to minister to their needs is reversed when the weak and naturally insignificant become too small to be recognized or controlled, and thereupon parasitism develops, in which the nominally weak prey upon the strong. A counterreaction follows when the higher organisms become able not only to understand the nature of the parasites, but to war against them.

Treatment of Pneumococcus Meningitis.—Kleinschmidt treated a case of this condition, which was secondary to a pneumococcus angina, by means of repeated lumbar puncture and the intravenous injection on two occasions of Römer's serum and urotropin. The patient recovered.—*Medizinische Klinik.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

The reader is referred to the many excellent textbooks for the details of physical diagnosis, as it is the writer's desire to limit the suggestions in this and following contributions to the practical points which arise in connection with examinations for life insurance.

General Methods.—A strong and persevering effort during about the last ten years to raise the standard of life insurance examinations has been rewarded with substantial success. The quality of this work is now of the high order that would naturally be expected from the class of men who represent the different companies, but it still remains true that the best of examiners will occasionally forget the importance of scrupulous care and constant vigilance in their examinations when pressed by the other numerous duties incident to the life of a busy practitioner. Then, again, though the majority of examiners are men of recognized integrity and ability, candor compels medical men themselves to admit that the efforts of some of their poorly equipped or weak fellow-practitioners have not always reflected credit on the profession, either in their capacity as the family physician or as a life insurance medical examiner. The writer has been interested for a good many years in the improvement of the medical situation in so far as it related to life insurance medicine, and some of his personal experience may interest, it certainly will surprise, most examiners by showing to how low a plane poor work of this kind may reach and what the companies have had to contend with in some localities. The conditions referred to were usually encountered in sections of the country where circumstances, chiefly financial, forced men up to the last few years to seek a medical training in the local mushroom colleges which disgraced the land, especially twenty or thirty years ago. Graduates from concerns of this kind were sent out with the most superficial ideas of physical diagnosis, and if they were not tremendously inspired with ambition and also settled in obscure places where they missed the advantages of interchange of thoughts with better equipped men, they almost inevitably fell into deep ruts of empiricism, treating fevers with calomel and quinine irrespective of the nature of the disease which they rarely understood. With age and personality in their favor these men were often regarded as the most prominent physicians in their neighborhood, yet it was not uncommon to find them without the faintest idea of the requirements of physical examination or urinalysis, or even the necessary apparatus. They seldom required the applicant to remove the coat or vest for the examination, or, still worse, omitted the ceremony of a physical examination and urinalysis altogether, this complacent and congenial frame of mind arising especially when the examiner and the applicant were friends or fellow-members of some order or society. The names of these men have gradually disappeared from the lists in the endless weeding out process and been replaced by those of examiners with a higher sense of duty and better qualifications.

The examination of an applicant is of little value unless it is carefully and completely made under the following favorable conditions:

1. Privacy.—The advantages of privacy are obvious; namely, that there will be no hindrance to the applicant giving out information that he would hesitate to impart in the presence of other persons, and there will also be no disturbing element to distract the mind of the examiner. Privacy should always be insisted upon. The only exception is in the case of a woman applicant, in which event the presence of some friend during the physical examination after the questions have been answered is permissible.

2. Absence of Noise and Bustle.—This will not only help the ear of the examiner but will also allow him to concentrate his faculties on the work in hand. The action of the examiner will be upheld by the home office if he refuses to go on with the examination until a suitable place is selected.

When photographing the subject for the original of this cut, the chest was so completely exposed that the stethoscope could be applied directly over the apices without touching any clothing.

3. The Removal and Proper Arrangement of the Applicant's Clothing.—The best of diagnosticians and the keenest of ears will surely fail at times to detect some of the signs of disease through thick clothing, especially in the early stages of pulmonary lesions and in some forms of heart disease. Moreover, the clothing interferes with ocular inspection, palpation, and percussion. Nevertheless, the writer ventures the statement that fully 50 per cent. of examinations are made through thick undershirts, two shirts one of which is often starched, or even through shirts and vest. The fear of offending the applicant by asking him or her to remove sufficient clothing to permit an examination of any value often deters the examiner from making the request. This danger is purely an imaginary one provided the examiner goes about it in a calm, polite and diplomatic way. Home office examiners whose duty brings them in contact with thousands of applicants of both sexes in their homes or at their places of business, invariably and with-

out any exception secure enough exposure of the chest and abdomen to insure the proper conditions, and this arrangement is always cheerfully assented to without any visible signs of annoyance or irritation. The best method for arranging the clothing is shown in the accompanying cut.

Having removed the coat and vest, the suspenders are dropped. Both shirts are then rolled up to the level of the clavicles and held there by the applicant, leaving the examiner free to proceed with his examination of the chest and abdomen. In doubtful cases or when a starched shirt is worn, it may occasionally be necessary to ask the applicant to remove the outer shirt so as to allow a thorough auscultation at the apices. In most cases, however, the first procedure of rolling the shirts up will meet all requirements. When examining the back the shirts are similarly rolled up, the applicant holding them by a hand extended back over each shoulder. When women are to be examined there should be no clothing above the waist other than a sack or robe of some stuff thin enough to allow a satisfactory examination. Corsets should invariably be removed. The writer has examined hundreds of women in all classes of society and has never experienced any difficulty in having his requests for such an arrangement cheerfully granted.

The examiner should always remember that the home office authorities are too pressed for time to be interested in his mental processes. It is their function to secure information as to whether or not the applicant is insurable and they will usually entertain a feeling of gratitude toward the examiner who limits his answers to "yes" or "no" or to short concise ones if some further explanation is necessary. Nothing is gained when an examiner theorizes on or reports some condition which, while it is not exactly according to rule, is not pathological to the slightest degree, such as, for instance, the occasional difference found on percussion or auscultation between the sides of healthy chests, a purely cardio-respiratory heart murmur, and many others. As long as the examiner thinks such statements are important enough to appear in the medical report, they must be noted at the home office and the matter cleared up through further correspondence with consequent delay. The examiner is depended upon to ascertain whether or not the irregularity is caused by some pathological lesion or by some condition actually detrimental to the applicant as an insurance risk. There may be reasonable doubt in which case he is always entitled to as much time as he needs and he is justified under such circumstances in requesting further interviews with the applicant in order that he may ascertain the real nature of the trouble; but when he has made up his mind definitely he should simply report any abnormality present or recommend the risk, as a rule, without further comment. If the examiner with the applicant before him and his ear to the chest is not able to arrive at a conclusion, the medical director at his desk will hardly be in a position to come to any decision with only indefinite or ambiguous statements before him.

Aural Disease and Life Insurance.—Milligan and Wingrave state that the relation of ear disease to life insurance is a very difficult subject to discuss, as it involves many considerations, including the personal equation. A patient with evidence of long-standing suppuration of the middle ear with occasional labyrinthine disturbance, who obstinately refuses to undergo radical treatment, should not be accepted at any rate, but after successful treatment and an interval of freedom from all symptoms he may be accepted at a moderately increased annual premium. The authors believe that it would be extremely unfair to establish an inelastic standard of fitness or unfitness, particularly in view of the rapid progress of otological surgery. According to Swift, a history and the existence of labyrinthine disease, however obscure, should always be penalized, for although the disease itself may not directly shorten life, it may do so indirectly. The following are regarded as indications for absolute and unqualified rejection: (1) unequivocal signs of syphilis, tuberculosis, lupus, or neoplasm in the ear itself; (2) exostoses and intractable stenosis of the meatus, with or without existing discharge; (3) all suppurative middle-ear cases with vestibular complications; (4) evidence of caries or necrosis of any part of the temporal bone, with or without facial paralysis; (5) any form of aural trouble associated with an existing or past leucemia, tuberculosis, syphilis, or arteriosclerosis; (6) whenever the aural discharge is accompanied by disease of the nasal accessory sinuses; (7) all primary or secondary infections of the labyrinth with or without history or evidence of intracranial disease. Penalized acceptance may be advised in those who have undergone the radical operation and in whom there has been no recurrence of any symptoms whatever for a period of two or three years, and no evidence of cholesteatomatous accumulation or sepsis. But there should be some hesitation in accepting even with an increase of premium any such patient who suffers from recurring attacks of eczema. Deferred consideration pending complete cure should be applied to: (1) all cases of acute and chronic eczema of the meatus and auricle, especially those showing a tendency to stenosis; (2) cases of subacute and acute primary mucopurulent inflammation of the middle ear, especially those cases accompanied by nasal and nasopharyngeal obstruction. The above considerations may serve as a guide, without fixing any arbitrary distinction, which is impartial alike to the insurance company and to the applicant.—"A Practical Handbook of the Diseases of the Ear."

Life Insurance in India.—Adrian Caddy, surgeon to the Hindu Marwari Hospital, Calcutta, presents interesting points which indicate the differences between individuals presenting themselves for examination for life insurance in England and those who are examined in India. In regard to the native lives Caddy finds that the native is usually a shorter man than the European, that height for height the native weighs the same on an average as the European, and that there is no evidence to show that his tissues are any lighter than those of a European. The native is very subject to glycosuria, due probably to his carbohydrate diet; he is also liable to develop hydrocele, but the reason for this is not evident. The author is of opinion that opium and hemp drugs are not commonly consumed by the insuring classes. He maintains that Europeans do not acclimatize in the tropics, and submits as a proof of this statement the inability to withstand the tropical sun without any head covering, and after years of residence in hot climates there seems to be a greater liability to sunstroke than on arrival. He further contends that the children of Europeans who have been sent "home" when four or five years old for their education are generally not so fine physically as their parents, owing to the debilitating influence on their constitutions of the tropical climate at an important growing period of their lives. These are points which have an important bearing as regards the rating on candidates for life insurance. Little has been written on life insurance in India, and Caddy's observations are worthy of attention.—*Lancet*, February 3, 1912.

Book Reviews.

Die Storungen des Farbensinnes, ihre klinische Bedeutung und Diagnose. Von Dr. Hans Kollner, Privatdozent an der Universitäts Berlin, Assistant der Universitats-Augenklinik. Mit 33 Abbildungen im Text und drei farbigen Tafeln. Price 14 M. Berlin: Verlag von S. Karger, 1912.

The work of Kollner constitutes a volume of 428 pages. It is a comprehensive review of the subject, evidencing a most careful and exhaustive study. The various conditions of the color sense are considered under the headings: "The normal color sense," "The congenital defects of the color sense," and "The acquired defects of the color sense." At the end of the volume a chapter is devoted to a discussion of the methods of examining the color sense. An extensive bibliography accompanies the text. The work is of interest to the scientist as well as to the medical man, but is of course of much more interest to those who are devoting themselves to the study and practice of ophthalmology. The work is one that must be read carefully to be fully comprehended; consequently it will not be popular with any but the student.

The Way With the Nerves. Letters to a Neurologist on Various Modern Nervous Ailments, Real and Fancied, with Replies thereto Telling of their Nature and Treatment. By Joseph Collins, Physician to the Neurological Institute of New York. New York and London: G. P. Putnam's Sons, 1911.

The readers of the Medical Record will probably recall the "Letters to a Neurologist" that appeared in these columns about two years ago. These are now presented in book form, and, as the title suggests, aim to present to the general reading public a popularized exposition of modern neurological science. No reader will fail to be interested, even charmed, with Dr. Collins' masterly exposition of a most difficult chapter in medical science, with his scholarly style and subtle humor. The general practitioner will find this a lucid epitome of current conceptions regarding nervous diseases, such as the relationship of neurasthenia and psychasthenia, the nature of sick headache, epilepsy, of depression, hysteria, ennui, and the dual personality. Letters of more popular interest are those on mental retardation in children, the moderate drinker, the repressed emotional woman, the idle well-to-do young man, the choice of a profession for a nervous youth, jealousy, and dipsomania. For their faithful portrayal of the professional types the letters on the "bedside manner" are masterpieces of humor and gentle caricature.

No one can justly question the value of popularizing medical knowledge, whether this relates to the means of preventing diseases of infectious nature or whether it is aimed to stem the rapid increase of nervous disease. At the same time one may doubt the wisdom of placing in the hands of a neurasthenic or hysterical individual a primer on insanity. Books on general medical topics for popular reading are valuable in proportion to the intelligence of the reader. If the latter, by virtue of information gleaned from these books, presumes to become his own doctor, the possibilities of ultimate harm are at once obvious. But the public craves knowledge on this subject as well as on other branches of medicine, and there is no reason why this craving should not be satisfied. The author has accomplished the task of writing a volume that adequately reflects the modern tendencies in neurology. More than this, it is a book of distinct literary merit, scintillating with wit and allusion.

Manual of Physiology. For Students and Practitioners. By H. Willoughby Lyle, M.D., B.S. (Lond.), F.R.C.S. (Eng.), Assistant Ophthalmic Surgeon to King's College Hospital, Surgeon to the Royal Eye Hospital, Ophthalmic Surgeon to the Royal Ear Hospital, Examiner in Physiology for the Primary Fellowship of the Royal College of Surgeons of England, Formerly Lecturer on, and Senior Demonstrator of Physiology in King's College, London. With One Plate and 135 Figures in the Text. Price $4.00. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1911.

The needs of the student and general practitioner are admirably supplied by this work, which represents a concise and at the same time comprehensive treatise on modern physiology. The bearing of the subject upon practical medicine and surgery is indicated whenever possible. The experience of the author as a lecturer on the subject at King's College, London, for sixteen years, has enabled him to study the wants of the student, and it would be difficult indeed to conceive of a better manner of providing the student, as the author has done, with a compact text-book on this extensive subject. The book is well written, clear in its statements, and amply illustrated. It may be recommended without reserve.

Über Moderne Syphilistherapie mit besonderer Berücksichtigung des Salvarsans. Von Geh. Med.-Rat Prof. Dr. A. Neisser, Dir. der Dermatolog. Univ.-Klinik und Poliklinik in Breslau. Price M. 1.50, Halle a.S. Carl Marhold Verlagsbuchhandlung, 1911.

In this concise and thoroughly up-to-date brochure of forty-six pages the author points out through the three discoveries during the past eight years, namely, *Treponema pallidum*, the ability to infect monkeys, and the Wassermann reaction, that the treatment of syphilis today is no longer purely empirical, but a rational one founded on objective facts. He advises instituting treatment at the earliest possible moment and advocates the abortive treatment. He is a firm believer in salvarsan, using it intravenously in repeated doses in conjunction with mercury.

Die Gonorrhoe des Mannes; Ihre Pathologie und Therapie. Ein Leitfaden fur Arzte und Studierende, von Dr. med. Wilhelm Karo. Berlin. Preis M. 2.80 Verlag von Julius Springer, 1911.

The author has neatly condensed his subject matter of gonorrhea in the male as systematically as could be expected in a book of 100 pages. He divides his book into six parts, namely: I. Anatomical remarks. II. Clinical Aspect of Acute Gonorrhea. III. Treatment of Acute Gonorrhea. IV. Complications of Acute Gonorrhea. V. Chronic Gonorrhea. VI. Marriage Consent in Gonorrhea. Each part is subdivided into chapters dealing respectively in a brief and concise manner with his own and other modern methods of diagnosis and treatment of gonorrhea in its different stages. The chapters on treatment deserve particular mention since they present the details usually sought for by the student and practitioner. In a book of this size the author naturally has been unable to give the space that the treatment of chronic gonorrhea deserves. He does, however, outline the salient factors necessary for its successful treatment. The absence of illustrations, and omission of citations of personal cases and statistics, gives the reader a comprehensive understanding of the subject.

Traité de la Blennorrhagie et de ses Complications. Par le Dr. Georges Luys, Ancien interne des Hôpitaux de Paris, ancien assistant du Service des voies urinaires a L'Hôpital Laribosière, Laureat de la Faculté de L'Académie de Médecine. Avec 202 figures dans le texte et 3 planches en couleurs hors texte. Price 12 francs. Paris: Octave Doin et Fils, 1912.

We have in this book of twelve chapters covering 529 pages the subject of gonorrhea and its complications. The author has been liberal in giving space to the most important phases of this disease. He begins his work with an interesting chapter on the History of Gonorrhea, quoting from the various works of numerous early observers as regards their primitive and rudimentary views on the subject. In his second chapter on the Dangers of Gonorrhea he shows by authentic citation of cases from his and other modern observers' experiences how "the reckless, the ignorant, or the guilty infected individual" has conveyed the disease to his wife and thereby "has soiled, crippled, or killed her." The sociological and medicolegal aspects of gonorrheal infections are ably discussed. The third chapter deals with the gonococcus, its mode and frequency of infection, methods of staining and cultures, as well as its toxic effects on the general system. In the succeeding chapters may be found described in detail the anatomy, pathology, symptomatology, methods of diagnosis, and complications of gonorrheal and non-gonorrheal infections. A separate chapter is devoted to gonorrheal infections in women and children. With characteristic national thoroughness the author has given merited space to the treatment of acute and chronic gonorrhea. Like the majority of modern urologists, he favors the irrigation method of treatment as against the use of the hand syringe and balsams alone in the acute infections. He has described in detail every modern method of treatment used in chronic gonorrhea. It is surprising that the author has not devoted some space to the well-known tests for the proofs of the cure in gonorrhea. Urethroscopy occupies a prominent place, covering 100 pages in this text. Luys urges its more frequent practice and considers it indispensable in the diagnosis and treatment of chronic urethral infections. Besides a description of his urethroscope, a modification of the Valentine instrument, he has illustrated a number of the early models as well as the modern types, with a description and criticism of each. The 202 cuts and illustrations with 3 colored plates are clear, thereby lending an intelligent interpretation of the text.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK

242d Regular Meeting Held November 3, 1911.

THE PRESIDENT, DR. J. W. BRANNAN, IN THE CHAIR.

Large Mediastinal Lymphosarcoma Arrested.—Dr. R. ABBE showed a boy operated upon by him six months ago. The patient was in a critical condition at that time, owing to a large tumor in the mediastinum and left chest, which extended to the third rib in front. The operation consisted in the removal of part of the seventh rib, and a considerable part of the tumor which grew outside the chest wall, after which applications of radium were made by the insertion of eight long slender tubes five inches into the mediastinal tumor. Dr. Abbe stated that there had been no return of the tumor at the site of removal and that the general condition of the patient had become such that the boy could attend to the ordinary amusements and occupations of his age. Then followed an exhibition of a photograph which showed the area of dullness in the patient, together with two *x*-ray negatives—one a front and the other a side view of the tumor. Dr. Abbe said that the tumor had in all probability begun in the mediastinum. Radium had been applied only once, six months ago, at the time of the operation. The photograph showed displacement of the heart, so that the apex beat was under the right nipple.

Demonstration of the Perfect Result of Beatson's Operation at Six Months.—Dr. ABBE presented a patient aged thirty-two years and apparently in perfect health who had been operated on four years before for mammary carcinoma. Two years later recurrent nodules appeared about the scar. Six months ago the patient had disseminated carcinosis as follows: On the side of the chest scores of carcinomatous nodules had merged into a dense group, the area of one's hand, and fixed upon the chest wall. Many enlarged glands were felt above and below the clavicle. In the remaining part of the chest a tumor the size of an English walnut was felt with enlarged axillary nodes and over the shoulder on the same side was a typical malignant subcutaneous nodule. The patient was cachectic and unable to continue her work. Oophorectomy was done in time. As early as the fifth day some of the recurrent nodes began to flatten and to umbilicate. Rapid changes were observed during three weeks, when many nodules had entirely disappeared. The patient spent the summer in the country and had lately returned for observation with apparent restoration to perfect health. At the present time the patient showed entire disappearance of every trace of malignant disease. One ovary at the time of removal was healthy, the other showed a pea-sized nodule of typical carcinoma. Dr. Abbe added that the results of the Beatson operation had shown that recurrence might be expected from six months to three years after oophorectomy. Even this picture of temporary favorable outcome of organotherapy which might be expected in one-third of all cases justified the operation and further hope might be justly held out that in these late recurrences the beneficial results of the *x*-ray and radium might prove helpful.

Chronic Vernal Catarrh.—Dr. ABBE showed two cases of five which had been submitted to him for radium treatment, having resisted all ordinary methods. The worst case was that of a young man of fourteen who had acquired the disease in childhood; he had an enormous thickening of the mucosa of the eyelids with granulating masses in clusters embedded in thick mucopus, and photophobia and pain. One eye only was treated at first by radium, with applications for five minutes every two months; it had remained perfectly cured. Later treatment of the other eye, begun recently, had about cured that also. The second patient shown had lately begun treatment and demonstrated the prompt beneficial effect. All five cases demonstrated the curability of this disease by the use of radium.

Advanced Mammary Carcinoma: Rapid Reduction Under Radium Treatment.—Dr. ABBE demonstrated four colored plaster-of-Paris casts of an inoperable cancer of the breast, in a patient of seventy-six years. The tumor was large, nodular, ulcerated, painful and bleeding, and attached to the chest wall. The first cast was taken before treatment two years ago. Radium was applied at intervals of three months; the ulcers immediately healed and retrograde changes began. Casts were taken every six months. Now only a few marginal spots remained with soft cicatrix.

Dr. C. L. GIBSON said that we might explain the arrest of such processes by considering that a tumor was a parasite of the body, and anything that interfered with the function or nutrition of the parent would be neglected in the parasite. Injections of various sera often produced changes as shown by the reaction of the kidneys. The effect of doing any kind of an operation or the giving of an anesthetic might produce such changes, *e.g.* we knew now that patients were cured of osteomalacia not by the ovariotomy, but by the administration of the chloroform.

Hospitals and Typhoid Carriers.—Dr. J. W. BRANNAN made this communication. He said that some three months ago his attention was attracted by an article by Meakins of Montreal in the *Canadian Medical Association Journal* entitled "Typhoid Bacillus Carriers." In view of the danger of typhoid carriers to the public health, Meakins urged that every typhoid fever patient in our general hospitals should be examined bacteriologically before discharge, and should be kept in the hospital or under strict observation until the excreta were free of typhoid bacilli. Patients under the care of physicians in private practice should be watched and frequently examined. Impressed by the suggestion of the Canadian writer, Dr. Brannan had requested Dr. Charles Norris, the director of laboratories in Bellevue and its allied hospitals, to have the feces and urine of all cases of typhoid fever examined during convalescence. Eighty-one cases in all were examined and of these eight, or about 10 per cent., had typhoid bacilli in either feces or urine or in both at some time during the course of the disease. All patients were bacteriologically free before discharge from the hospital. Had it been necessary to discharge any patients while still carriers it had been Dr. Brannan's intention to report their names and addresses and occupations to the Health Department in order that they might be kept under observation by that department.

Regulations of typhoid carriers had been enforced in parts of Germany for a number of years. In the southwestern provinces there was probably no case of typhoid fever released from control until the bacteriological examination of the feces and urine had proved negative. In England, also, typhoid carriers received a great deal of attention, especially in the English army. After treatment for a period of three months, if it was found that the soldiers were still carriers, they were given the opportunity of entering the hospital or of being discharged. In case of discharge notification was sent to the medical officer of health of the district in which the soldier was going to reside. In the service in India two convalescent depots were established several years ago, to which the convalescents of certain military stations were sent. After the establishment of these convalescent depots, namely, Wellington and Naini Tal, it was found that the admissions of typhoid fever from all stations which sent their convalescents there showed a reduction of 9 per cent. from the figures for 1907, whereas the remaining stations showed an increase of 26.6 per cent. In the endeavor to sterilize typhoid carriers various methods of treatment had been tried, such as the use of lactic acid bacilli, acidifying the

urine, the administration of antiseptics, the use of the *x*-ray, and the employment of vaccine. The surgeons of the English army had reported the following results of the use of these five different means of treatment: (1) Lactic acid bacilli caused only a temporary disappearance of the typhoid bacilli. (2) Acidifying the urine failed to cure typhoid bacilluria. (3) The administration of antiseptics invariably brought about a decided diminution in the number of bacilli both in fecal and in urinary carriers. This effect was much more marked when the maximum contact of the antiseptics with the bacilli was obtained by combining the treatment with low diet and aperients in the case of "fecal," and with diuretics in the case of "urinary" carriers. (4) The use of *x*-rays in the cases of gall-bladder infection seemed to have definite beneficial results. (5) Vaccines, like the lactic acid bacilli, caused only temporary disappearance of typhoid bacilli. It was suggested that the treatment by vaccines might have a better chance of success if combined with diuretics in the case of "urinary" carriers, and with *x*-ray treatment in gall-bladder cases. Sir Almroth Wright had pointed out that a vaccine was more likely to be efficient when the local conditions were so altered as to permit the fullest possible contact between the bacteriotropic products in the blood and the bacteria involved.

Dr. CHARLES NORRIS said that at the Fordham Hospital 17 per cent. of the convalescents showed the presence of typhoid bacilli in the stools; in the Harlem Hospital 11 per cent., while at Bellevue Hospital only 5 per cent. were found.

Dr. GIBSON asked whether the use of urotropin had proved successful in sterilizing the urine.

Dr. J. W. BRANNAN answered that it was considered a very useful drug as the result of several years' use, and was now used as a matter of routine.

Dr. W. JAMES remembered patients in which the use of urotropin produced disastrous effects; one patient had hemorrhagic cystitis.

Dr. J. C. ROPER then pointed out the fact that any inconvenience due to urotropin ceased by stopping the use of the drug.

Dr. L. B. BANGS stated that he had never seen serious inconvenience result from the use of urotropin, although he had seen cases of mild irritation of the neck of the bladder follow its use.

Dr. F. S. MEARA thought that antiseptic drugs were generally insufficient for the disinfection of the intestine, and that probably in the intestine as well as in the bladder and in the gall-bladder, there existed conditions favorable to the growth of the bacilli; conditions which he believed to be too far-reaching for the therapeutic effect of antiseptics or of the lactic acid bacillus, and that as they were practically outside the body, *i.e.* the tissues, were not amenable to the effects of vaccines.

Dr. J. C. ROPER recalled that some years ago at the New York Hospital some observers failed to isolate the typhoid fever bacilli from the urine of patients to whom urotropin had been administered. The quantity of the uric acid in the urine, he said, seemed to have an effect on the presence of the bacilli. It had been shown experimentally that typhoid bacilli grow very poorly in urines rich in uric acid. There was a very small amount of uric acid in the urine of typhoid fever patients during convalescence.

Dr. W. JAMES then asked whether Dr. Brannan had ever observed that typhoid carriers are case of difficult convalescence as compared with those who are not carriers. He recalled the case of a patient who had a long and difficult convalescence from an attack of typhoid fever; such patient remained anemic and feeble for several months and proved to be a typhoid carrier.

Dr. A. A. SMITH related the history of a case of cholecystitis in the third week of typhoid fever on whom an operation was done for relief. A fistulous opening was left from which bile passed freely which contained large numbers of typhoid bacilli. Urotropin was given to the extent of eighty grains daily with absolutely no effect in reducing the number of bacilli. The gall-bladder was finally removed and the patient left the hospital thoroughly convalescent. The cultures from the urine and feces became negative after the removal of the gall-bladder.

Dr. F. S. MEARA asked whether the use of vaccine proved beneficial in cases of colon infections, and said that in the three or four patients he had had under observation the local condition was not noticeably improved by the use of vaccine, while the general symptoms due to the absorption of toxins was greatly ameliorated.

Dr. BRANNAN, in closing the discussion, said that he had not found in the literature any observation that typhoid carriers had had an especially long and difficult convalescence. In fact, it appeared that many carriers had never had typhoid fever, but had apparently acquired the bacilli while taking care of people with the disease. In parts of Germany nurses and others in the care of typhoid fever cases were examined and a certain proportion had been found positive. As to urotropin, he said that ten years ago, when he was attending at Bellevue Hospital, it was the practice to give about thirty grains a day and he believed that this was still the practice. During the bacteriological examinations described above this was temporarily discontinued. In Europe, and especially in Germany, typhoid carriers had not been permitted to resume work in any occupation involving the handling of food or drink, such as that of cooks, bakers, dairymen, etc. In reply to Dr. Thacher, Dr. Brannan added that he also before reading the literature had expected to find better results from the use of vaccines in the treatment of typhoid carriers.

Recent Improvements in the Use of Radium.—Dr. R. ABBE read this paper (see page 255).

Dr. L. B. BANGS asked Dr. Abbe what was the difference, if any, between the action of the *x*-rays and that of radium.

Dr. ABBE replied that the first difference was in the fact that some tumors had improved under the action of radium treatment, which had not yielded under that of the *x*-rays, and that besides, radium could be applied where the *x*-rays could not. In answer to a question by Flexner, he said that the depressing action of radium on tumors was clearly demonstrated in the case of a woman with a recurrent growth attached to the ribs. The place of application was marked by a red spot on the dermatitis, and the tumor had disappeared within two weeks. In the experiments described in his paper on the oat seeds, the depressing effect could be appreciated by the result in the sprouting of the seeds, whose vitality was proportionately affected according to the distance from the radium. He had not yet studied on sections of tumors the question as to the depth to which radium action reached, but Wickham had demonstrated that it certainly reached inward one-half of an inch, though probably more effective applications could be obtained by keeping radium at a greater distance, inasmuch as by so doing there would be a gain because the application could be tolerated longer.

Orchitis with Unusual Features.—Dr. L. B. BANGS reported this case (see page 410).

Dr. W. M. HIGGINS recalled the great importance of the clinical data to throw light on the diagnosis of pathological specimens and reminded those present that at the Johns Hopkins Hospital it was a matter of routine to unite the clinical history to the anatomical specimens. Upon an examination of a small portion of the tumor taken from the superficial stratum he said he had had the impression that the case was one of epithelioma, but the next day after getting the clinical data and the examination of an-

other series of sections the condition proved to be chronic epididymitis with acute inflammation of the testicle, and that the trauma had destroyed the epithelium of the testicle. What he could not explain was why the testicle was free and why there were no signs of atrophy.

Dr. Bangs stated that he had unsuccessfully looked for the cause of the testicle being free and suggested that there might have been thrombosis of the blood vessels. Perhaps during the four days of residence in the country there had been torsion of the funiculum.

Dr. F. S. Meara stated that he had some time ago heard the reading of a paper on the torsion of the testicle that recalled this case, to which Dr. Bangs replied that there was no evidence of this condition in the case reported, although it might have occurred a long while before.

Dr. S. Flexner asked what was the nature of the histological structure of the fungoid growth from the scrotum.

Dr. W. M. Higgins reported that the tubules were obliterated, the section showing them being closed by leucocytes and red cells. In answer to the question of Dr. J. S. Thacher Dr. Higgins said that the color of the specimen was slightly red on the surface.

Dr. Abbe had seen but one case of gangrenous destruction of a testicle due to the torsion of the cord. It occurred in a young lad of eight years and required castration at the end of one week. The symptoms were those of acute severe orchitis without apparent cause, explained only at operation by rotation of the testicle clearly demonstrated as in ovarian rotation on its pedicle.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 2, 1912.

Dr. L. W. Hotchkiss in the Chair.

A Case of Fecal Concretion.—Dr. Forbes R. McCreery presented the patient and specimen which was removed. (See page 418.)

Gangrene of the Ileum Complicating Appendicitis.—Dr. Joseph Wiener said that a careful search of the literature had failed to reveal a single case on record similar to the one he wished to report. The patient was fifty-seven years old and had been in this country twenty-nine years. She had suffered from constipation for more than twenty years and had taken cathartics almost daily for the past fifteen years. In 1900 she had her first attack of abdominal pain, which subsided after four or five days. Four weeks later she had a similar but milder attack. Following this second attack there was no abdominal disturbance for five years. Then she had some slight abdominal discomfort but no pronounced attack. In June, 1909, she had a third attack of right iliac pain, associated with vomiting; this kept her in bed for a few days. In August, 1909, after running for a train, she complained of severe precordial pain, which persisted for a few days; ever since then any slight exertion brought on the precordial pain, which was associated with palpitation. In March, 1910, she awoke one night with vomiting, and pain in the right iliac fossa; she also had some fever. This fourth attack was more severe than the preceding ones and kept her in bed ten days. Following this attack there was almost continuous pain and discomfort in the right iliac fossa until June, 1910. During the entire summer there were no symptoms referable to the abdomen. October 15, 1910, the patient awoke with severe right iliac pain and vomited several times. On the day of operation she had severe pain all day, and vomited everything she took. No blood or mucus was noticed in the stools. Dr. Wiener first saw her in consultation October 17, 1910, with Dr. A. R. Stern of New York and Dr. Joseph Baum of Far Rockaway. While making preparations for the operation Dr. Howard Lilienthal of New York was called in consultation. They all agreed in the diagnosis of a perforative appendicitis. The patient was taken to St Joseph's Hospital, Far Rockaway. At operation the appendix was found below and to the inner side of the cecum, from which it had almost completely sloughed away. It was surrounded by a small amount of pus. A loop of small intestine was found to be completely denuded of its mesentery. The vessels in this portion of the mesentery had thrombosed, and there was no bleeding throughout the entire operation. The loop of intestine affected was in the ileum about ten inches from the ileocecal junction, and was about eight inches long. Owing to the presence of a peritonitis and of pus in the abdomen, Dr. Wiener did not believe the patient would survive an immediate intestinal resection. What was left of the appendix was quickly tied off, the affected loop of ileum was surrounded by gauze packings, and the entire wound was left open. Several strips of zinc oxide plaster were passed around the abdomen to prevent prolapse of the abdominal contents. The time of operation was about thirty minutes. On the third day there was a copious movement of the bowel. On the eighth day there was a foul discharge from the wound and on investigation they found that the loop of ileum in the wound had become completely gangrenous. It was cut away without any pain, and thereafter all stools came from the wound. Three weeks after operation the wound was granulating nicely. The finger in the wound could feel two openings in the intestine. As the wound contracted the two openings came closer and closer together. It did not seem possible that nature could ever bring about a spontaneous anastomosis of the two ends of the gut in the wound, but yet they were anxious to keep the distal loop patent, and the granulating wound had a tendency to cover it over. The wound granulated rapidly and soon almost all the stool was coming through the rectum. December 20, 1910, the patient was transferred to Mount Sinai Hospital. They were unable to understand how the two loops of intestine could have grown together, after such an extensive gangrene, without forming a stricture of the gut. Subsequently they found that such a stricture had indeed been formed, and it was only the patent fistula that prevented its giving symptoms. On January 18, 1911, there was little discharge from the fistula and the patient was allowed to go home. After a few days there were symptoms of partial intestinal obstruction, nausea and abdominal cramps, but these promptly subsided when the fistula which had apparently closed reopened and discharged profusely. The patient was readmitted January 24, 1911. As no further improvement was to be expected without interference, they decided to do an ileocolostomy. They decided that if the wall of the gut was in good condition, and if the anastomosis could be rapidly done, they might attempt a closure of the ileum. On March 6, 1911, a side to side ileocolostomy was performed. The method of suture was that of the Moynihan gastroenterostomy. The opening was made about an inch and a half long and the abdomen was closed without drainage. They hoped that most of the fecal current would be sidetracked through the new opening, and that they would then be able to bring about a closure of the fecal fistula still remaining, but they were disappointed in this. A third operation was performed on April 24, 1911, 188 days after the first, and an excision of the ileum, cecum and ascending colon was performed. About ten inches of ileum and twelve inches of large intestines were removed. On July 5, 1911, the patient left the hospital with a completely healed wound. Six months later the wound was still firmly healed, the bowels moved daily without cathartics, and her general condition was excellent. Dr. Wiener reported this case *in extenso* (1) because a fairly thorough search of the

literature failed to reveal a similar case; (2) because it showed that nature could bring about an intestinal anastomosis in a wound, even after complete gangrene of eight inches of gut; (3) because it showed the futility of expecting the fecal current to be completely diverted by a lateral ileocolostomy, without occlusion of the ileum; (4) because it demonstrated the great advantages of two or three stage operations.

Experimental Study of the Effect of Ureteral Obstruction on Kidney Function and Structure.—Dr. Edwin Beer presented this paper. The work was begun four years ago with the purpose of determining, if possible, how long a ureter might be tied off before making a ureterovesical anastomosis without sacrificing the functional integrity of the involved kidney. The work was done on sixty dogs in the Surgical Research Laboratory of Columbia University. A series of experiments was made with the object of determining the effect of direct injection of cultures into the ureter after extraperitoneal exposure without in any way injuring its lumen by artificial stenosis. Colon bacilli were injected through a very fine needle. The involved kidney and ureter were removed at varying times and regularly showed well-marked hydronephrosis and hydroureter. In the earliest case the kidney was examined nine days after the injection and the organ was enlarged and moderately dilated. In another case, after fourteen days, the kidney was removed and it was practically normal except for pronounced hydronephrosis. In another case, after twenty-one days, a good sized hydronephrotic sac was present. In none of the cases were abscesses produced in the kidney parenchyma. A second series of experiments seemed to show that hydroureter and hydronephrosis of an extreme degree, in time leading to complete parenchymatous atrophy, followed the injection of infectious organisms above a stenosis. If the same technique was followed as in the first series of experiments, plus a complete or incomplete ligature of the ureter, whether with catgut or with silk, an extreme degree of distention of the pelvis and ureter followed, unless the injected bacteria were too virulent when pyonephrosis or pyelonephritis and early death followed. The early pictures were very much like those in the first series of experiments. Thus in five days a moderate hydronephrosis had developed in one case. In another case there was a marked dilatation with some perinephritis after 11 days. In another case the same picture was found after 12 days. In cases lasting 35 days, a very large hydronephrotic sac developed despite the use of a catgut ligature in producing the stenosis. In still another case, after 56 days, nothing but a large sac was left representing the destroyed organ. A third series of experiments seemed to show that after developing primary hydroureter and hydronephrosis of a mild degree, the kidney underwent atrophy if the ureter was tied and no infection was superadded. If the same technique was used as in the second series of experiments and no organisms were introduced into the ureter there was a primary dilatation above the stenosis, which gradually receded after the first two or three weeks and the pelvis became folded upon itself and the kidney parenchyma gradually atrophied. This atrophy became so complete that at the end of five months the excluded kidney was nothing more than a firm fibrous mass measuring from pole to pole one inch and from sinus to convexity one-half inch, with folded and enlarged pelvis and ureter. From this series of cases it seemed likely that the excluded organ was able to secrete up to about the third week as evidenced by the dilatation and distention of the pelvis and ureter up to this date. It also appeared that after three weeks the function was materially impaired as the distention, probably an evidence of secretory activity, disappeared. Chemical examination of the fluid in the distended ureter showed various amounts of urea, which seemed corroborative of this viewpoint. Fluid removed three weeks after ligature showed no urea in one case; in another, fluid removed 24 days after ligature showed only .005 gm. per c.c.; whereas 14 days after exclusion, in another case, urea was as high as 5 per cent. A fourth series of experiments seemed to show that if a kidney was excluded up to three or four weeks and then the ureter implanted in the bladder, the kidney seemed capable of carrying on all the excretory work of both organs. To test adequately the functional capacity of the reimplanted kidney it was necessary to remove the other kidney. Cystoscopic examination with indigo carmine, though repeatedly made, could not be accepted as conclusive evidence of renal adequacy or inadequacy. Consequently nephrectomy of the second organ was performed. In human surgery no such test would be required. If one could reimplant an excluded kidney that had only 50 per cent. of the total renal capacity, it was that much gain, as all cases coming into this category must from the very premises have a second adequate organ. Dr. Beer related the history of a number of these experiments in detail. They showed that one dog lived very satisfactorily with the right kidney, which did all the necessary excretory work even though it had been excluded for 30 days. In another case, he excluded the kidney for 37 days, and when it was tested by the removal of the other kidney it excreted four days after the nephrectomy 650 c.c. of urine, which on testing was alkaline in reaction, contained a faint trace of albumen and 1.6 per cent. urea. Subsequently this animal developed signs of insufficiency, and vomiting set in, followed by anuria and death. From this experimental data it was evident that even after three or four weeks' exclusion of a kidney sufficient parenchyma was present to carry on the work of the organ. Whether these results in dogs could be transferred to human beings experience alone could tell. The knowledge gained, however, was suggestive, and in the future if an operator resorted to ligation of a ureter he must bear in mind the fact that the excluded kidney might be made useful again if an anastomosis was made within three or four weeks of the original exclusion.

Dr. Henry Dawson Furniss thought the paper was of the utmost interest, and he had seen five similar cases. A very important point that came up was how the kidney could functionate after such ligation had been performed. Dr. Furniss wondered if the dilatation resulting from the ligation of itself produced the cystitis in the dogs. In a number of cases in which there had been a severe cystitis, after the cystitis had cleared up, there was found a marked dilatation, particularly marked in five of his cases. Many of these obstructions were due to stone. He reported two cases in which there was an obstruction of the lower end of the ureter with a marked dilatation of the ureter. In another case of obstruction of the ureter the solution used did not appear until after twenty-five minutes, and he hoped that after a second operation this patient would be returned to health. In many of these cases no infection took place and pain in the side was seldom complained of.

Dr. Joseph Wiener asked if it would not be worth while to take a series of cases and do as Dr. Beer did, but not to do a nephrectomy, and make studies on such a series. In the cases where infection of the kidney occurred it would be worth while to re-implant the ureter.

Dr. John Gerster stated that in certain experiments upon the ureters of dogs performed at the pathological laboratory of the College of Physicians and Surgeons, Columbia University, he had obtained results confirming those of Dr. Beer with infected urinary passages, namely, the production of enormous hydronephroses. In these experiments Dr. Gerster had succeeded in implanting pieces of the femoral artery between the divided ends of the right ureter in each case. The Carrel technique of end to end

blood vessel suture was employed by means of a small plastic portion of the peritoneum. Primary union was obtained in each case, and no peritonitis followed. It was found that although the urine passed through the implanted piece of artery immediately after the anastomosis within a week, cicatricial contraction set in which resulted in complete obstruction. The cicatricial contraction of blood vessels transplanted into the urinary passages (ureter and urethra) had also been observed abroad. All the dogs suffered from general bacterial infection, distemper, etc., which promptly led to the infection of the blocked side of the urinary system. The specimens which were passed around showed the kidneys, ureters and bladder removed *en bloc* in each instance, with varying degrees of hydronephrosis upon the obstructed side.

Fracture of the Cuboid Bone.—Dr. FORBES R. MCCREERY reported this case. (See page 418.)

A New Sigmoidoscope.—Dr. FRANK C. YEOMANS demonstrated this instrument. He said that hitherto the practical methods of direct illumination of the sigmoidoscope were by small electric bulbs carried near the distal end of the tube on insulated carriers. He had adopted the method of direct lighting as devised by Dr. Hayden in his urethroscope to the sigmoidoscope. The tube was 14 inches long, graduated in inches; it was ¾ inch in diameter, and was fitted with a large flange at the proximal end, which was perforated by a small auxiliary tube and joined the main tube at an angle. A light carrier fitted tightly into the auxiliary tube and the substantial incandescent bulb was covered with a capsule bearing a plano-convex lens so set that the collected rays were refracted at a compensating angle to the light carried. This lens projected only into the main tube and in no practical way interfered with the vision or the passing of instruments for examination, diagnosis, or the treatment of lesions of any part of the bowel below the apex of the sigmoid. The ocular end of the tube was closed hermetically by a plug which contained a glass window to magnify the illuminated field at the distal end of the tube. By attaching a hand bulb to a small offset at one side of the plug, the bowel could be dilated with air to any desired degree. The same light carrier and plug fitted shorter tubes and those of larger diameter. The points of excellence in the instrument were the simplicity of construction and the ease with which it could be sterilized by boiling. Strong electric lamps were connected with it

---

SECTION ON PEDIATRICS.

Stated Meeting, Held February 8, 1912.

DR. WILLIAM SHANNON IN THE CHAIR.

Case of Secondary Anemia.—Dr. CHARLES HERMANN presented a baby two years of age, whose family history was negative. The child had been breast-fed for six months and had had pertussis and some digestive disturbance. In July, 1911, when he was eighteen months of age, he was brought to the Babies' Hospital because of enlargement of the abdomen. The child had marked anemia; the spleen was six inches below the costal margin in the axillary line, and the liver one and one-half inches below the costal margin in the mammary line. At this time examination of the blood showed hemoglobin, 40 per cent.; red blood corpuscles, 2,800,000; white blood corpuscles, 13,000. Thirty nucleated red blood corpuscles were found in 300. The patient began to improve and this improvement continued until he was discharged in December, when he weighed 21 pounds and 12 ounces and the spleen was only three and one-half inches below the costal margin. Examination of the blood at this time showed hemoglobin, 70 per cent.; red blood corpuscles, 5,280,000, and only an occasional nucleated red cell was found. It was sometimes difficult to determine the primary cause of this condition. Syphilis, tuberculosis, and chronic digestive disturbances might be absent; and, furthermore, many cases of these affections were not accompanied by these blood changes. Six years ago in discussing such a case he had suggested that there was probably a congenital defect in the blood forming organs. A certain number of these cases gave a history of anemia from birth and the fact that the anemia appeared a few months after birth did not preclude the possibility of the cause acting from the time of birth. Infants were born with a certain amount of reserve iron in the liver and in twins or premature infants this amount would probably be less than normal and after a few months of an exclusively milk diet would be exhausted. Under normal conditions the blood-forming organs might be able to meet the demands, but if an intercurrent disease attacked the child they might not be able to do so. This would explain the onset of the anemia after certain constitutional diseases.

A Case of Splenomegaly.—Dr. CHARLES HERMANN presented this patient, a boy twelve years of age. His parents were healthy and he was one of eight children all living and healthy but one that died of convulsions in infancy. The patient had had measles, but no manifestations of syphilis and no chills and fever. The mother said that she had noticed the enlargement of the abdomen since the child was four years of age. Dr. James had seen the boy and diagnosed his case as one of splenic anemia. At this time the spleen extended one-half inch beyond the middle line and three inches below the level of the umbilicus; the liver extended two inches below the costal margin in the mammary line. The blood examination showed hemoglobin, 75 per cent.; red blood corpuscles, 4,390; white blood corpuscles, 4,000; polymorphonuclears, 70 per cent.; lymphocytes, 29 per cent., and eosinophiles, 1 per cent. The cervical, axillary, and inguinal nodes were palpable, but not distinctly enlarged. During the last five years the blood had been examined a number of times and the hemoglobin had been found to vary from 30 to 75 per cent.; at present it was over 50 per cent. The red cells had varied from 2,560,000 to 4,600,000, and were now 4,000,000; the white blood cells from 2,400 to 6,800, and were now 4,800; the polymorphonuclears from 51 to 70 per cent., and the lymphocytes from 29 to 48 per cent. The cells showed no abnormal changes in shape or size and the Wassermann and von Pirquet reactions were negative. During the last five years there had been no marked changes in his general condition or in the size of the liver or spleen, but on one occasion he had vomited a large quantity of blood and had blood oozing from the gums after having had a tooth pulled. He had gained 22 pounds, weighing at present 66 pounds. In this case three conditions might be possible, splenic anemia, Banti's disease, or the primary splenomegaly of Gaucher. The absence of ascites could not be positively against Banti's disease, for it was characteristic only of the third stage of that disease. However, they should expect some changes in the urine, which examination had shown to be normal, and the large liver so early in the disease would be unusual. The lack of other cases in the family was against primary splenomegaly. After having observed the patient for five years he was inclined to adhere to the original diagnosis of splenic anemia. Mercury, quinine, and arsenic had been employed without marked effect in this case. The *x*-ray treatment had also been employed without any noticeable change in the size of the spleen or the general condition of the patient. If this condition became worse it might be advisable to remove the spleen. A certain number of cases had shown distinct improvement after this operation.

Dr. NATHAN E. BRILL said he would confine his remarks to the second case as that type of associated enlargement of the spleen and liver were especially interesting to him. These enlargements were enveloped in much obscurity, especially when there was no constitutional in-

fection as tuberculosis, syphilis, or leucemia. It was almost useless to attempt an explanation of the pathology and pathogenesis of diseased conditions of the spleen until more was known of its physiology. This patient clinically appeared to present an entity to the possibility of diagnosing which he had called attention and to which he had also given the name of its discoverer, Gaucher. Dr. Brill believed that the boy was suffering from the Gaucher type of splenomegaly. The pathology of the condition was unique because the liver, the spleen, the portal system, and, as he had been the first to show, the bone marrow underwent a peculiar endothelial transformation. The proliferating endothelium showed cells whose appearance was characteristic and so far as he knew were not imitated by any other disease of those organs. The splenic parenchyma was changed into alveolar spaces filled with these cells which lay loosely therein. The cytoplasm was very abundant and therefore the cells were particularly large and presented a glistening homogeneous striated appearance. The same type of cells was found in the lymph nodes, in the bone marrow, the liver, and the walls of the portal vein in this disease. Clinically the subjects of this disease presented to his view a definite picture which differentiated it from splenic anemia and Banti's disease. These points of differentiation were the longer duration of the disease in the Gaucher type; its unpronounced anemia of a simple chlorotic type which became marked only toward the end of the patient's life, whereas it was an early and marked feature in splenic anemia; the peculiar and definite pigmentation of the skin where it was exposed; the entire absence of jaundice and ascites; the remarkable feeling of comfort and well being, though the spleen and liver might reach colossal size. The liver was also much larger in Gaucher's disease than in splenic anemia, and wedge-shaped conjunctival thickenings were present in every case of Gaucher's disease that had come under his observation, and his series had been larger than that of any other single observer. Clinically the disease appeared in two forms; one, a form affecting more than one member of a family, though the parents were not affected; and a second in which only one member of a family developed the disease. It might appear in infancy or be delayed in development until adolescence. Of thirteen cases reported up to 1908 Dr. Brill had furnished four and the diagnosis was made in these cases during life and so reported; it was subsequently confirmed by autopsy. Since that time he had seen two other cases, one in a young man whose sister also suffered from the disease and another in a gentleman of 43 years, who was the only one in a family of six brothers and sister thus affected. The blood picture was that of a simple mild anemia of the chlorotic type, but showing a decided leucopenia. Late in the disease hemorrhages from the nose, gums, stomach, and intestines might occur as well as ecchymoses on very slight injuries of the skin. The progress of the disease was much slower than in splenic anemia; one of his patients was still alive at the age of 46, though having had the disease since she was 10 years of age. Her spleen and liver almost completely filled the abdomen. Dr. Hermann's case had the enlarged spleen, the wedge-shaped conjunctival thickenings, the peculiar bronzing of the face, neck, and hands, the remainder of the skin of the body being normal, though a trifle pale. In these cases bile would not be found in the urine, though occasionally pathological urobilin of Jaffe was present. He disagreed absolutely with Dr. Hermann's statement that Gaucher's disease was not accompanied by hemorrhages from the mucous membranes of the body and he felt convinced that the patient presented was suffering with Gaucher's disease.

Dr. Charles Herman said, in closing the discussion, that he did not believe it possible in his case to make a positive diagnosis of primary splenomegaly from the clinical manifestations, only a pathological examination would be conclusive. The blood findings were certainly not characteristic. The slight pigmentation on the nose was by no means pathognomonic. Severe hemorrhage from the stomach had not been reported in any of the undoubted cases of primary splenomegaly of the Gaucher type.

An Unusual Case.—Dr. Charles Gilmore Kerley reported the case of a child, 6 years of age, who, while playing in the park, swallowed a watch. The speaker fished it out of the esophagus with a bent wire.

A Case of Food Allergy; Idiosyncrasy to Eggs, Almonds, and Oats, Due to Anaphylaxis.—Dr. Oscar M. Schloss read this paper, which was based on his observations of a patient who was now 8 years of age. The child's first experience with an egg was when at the age of 10 days he was given the white of an egg in barley water during an attack of diarrhea. There seemed to be no ill effects at that time. When 14 months of age, after having eaten a few mouthfuls of boiled egg, he began to cry and to claw his mouth. The tongue, lips, and buccal tissues began to swell and large urticarial wheals appeared about the mouth. If the child played with egg shells they produced urticaria on the hands and arms. These same symptoms invariably followed the administration of egg, no matter in what way it was taken, being noticeable even after he ate cake or roll glazed with egg. Two years ago he was given almond for the first time and the same symptoms followed as after the ingestion of egg. He had eaten other kinds of nuts without ill effects. Oatmeal also caused symptoms similar to those produced by egg. The problems for investigation in this case were indicated by the history. It seemed of interest to determine the constituents of the foods which were responsible for the toxic symptoms. It was found that cutaneous inoculation of the active substances produced a distinct urticarial wheal at the site of the inoculation which appeared in from five to fifteen minutes after the test was made. In stronger dilutions the active substance produced typical urticarial wheals by mere contact with the unbroken skin. The reaction was always immediate and always disappeared within one-half to one hour. Numerous control experiments were made to show that the reaction was specific and could not occur from chemical or mechanical irritation alone. Experiments with egg, almond, and oatmeal showed that the reaction was produced by the protein constituent only and that extracts and preparations free from protein were entirely inert. Experiments also showed that proteins from the same source varied in activity. Obviously the patient's idiosyncrasy, his hypersusceptibility to the food protein, was due to one of two causes: either he lacked some protective substance present in normal individuals or he was sensitized in the same manner as an animal became sensitized when given a single injection of a foreign protein. A number of experiments failed to demonstrate a lack of protective substance. That the condition was due to protein sensitization was shown by the fact that it was possible to sensitize guinea pigs passively by means of the patient's blood serum. Control animals developed no symptoms whatever when given the same amount of inactivated normal blood serum followed by the same amount of ovomucoid. The next problem was that of immunization. It seemed advisable to use a single protein for this purpose, as by this means it could be ascertained whether the patient's hypersusceptibility to the three dissimilar foods was in any way related. Ovomucoid was chosen as the protein for immunization and treatment was begun by the administration of 2 mg. of ovomucoid in capsules three times a day. The dose was increased very gradually at first and then more rapidly and the progress of immunization was determined by the cutaneous reaction. In a little over a month the patient

was taking 100 mg. of ovomucoid daily and the reaction began to decrease and was induced only by comparatively strong dilutions, 1-500, or stronger. At the end of two and one-half months' treatment the patient could eat one-sixth of an egg with no ill effects. From this time egg was given in small quantities daily. The proteose from oats caused no reaction in dilutions as high as 1-100 and oatmeal had been eaten a number of times with no resulting symptoms. These results seemed to indicate that the idiosyncrasy to the three foods was in some way related. During the treatment the patient was in comparatively good health and there were no symptoms referable to the administration of the ovomucoid.

Dr. HENRY KOPLIK said there was no doubt but that there were many children who could not take eggs and one should be very cautious in giving eggs to infants under one year of age. In exceptional cases not only eggs, but milk as well, were very badly borne. He had at present three patients under his care who could not tolerate milk. In one instance he had tried milk of various kinds, but none could be taken without the development of vomiting, purging, and other symptoms of serious import. He knew of two children who could not touch milk and were brought up without it. Strange to say, these children did not show the same symptoms when given mother's milk. Oatmeal acted against many children; and some could not tolerate beef juice. An interesting point was brought up regarding the v. Pirquet reaction or method in these cases; this might show what really was to blame; if these observations were confirmed they might lead to important results in the feeding of these children. The points throughout served as a warning not to force infants or children to take the various forms of foods which absolutely disagreed with them.

Dr. CHARLES GILMORE KERLEY said there were many children who could not take milk or eggs because of some special intolerance; in his experience the milk had given the more trouble. He cited an instance of a baby that died within twenty-four hours as the result of an effort to wean it and feed it cow's milk. There was no doubt but that frequently the giving of eggs or milk in young infants resulted fatally. He had seen one child practically killed by taking two ounces of milk. In another instance a child was given a 2 per cent. fat mixture and immediately signs of collapse appeared. In many instances milk could not be given until the child was 3 years of age. Some persons had idiosyncrasies for drugs and others could not take sugar without the production of disturbances. He related an instance where sugar produced hives.

Dr. ROWLAND G. FREEMAN said it was not generally appreciated how frequently cases of susceptibility to eggs in infancy occurred; it seemed to him that one-tenth of all babies showed some susceptibility. The speaker had seen a case in which rise of temperature, general urticaria, and edema of the ears, lips, and vulva occurred within three hours after the ingestion of an egg and quickly disappeared after the evacuation of the alimentary tract. They had not laid sufficient stress on the caution that should be exercised in giving the first egg to any child.

Dr. FLOYD M. CRANDALL cited an instance of two babies in one family who could not take milk without becoming very ill. Both children could take breast milk and were reared by a wet nurse.

Dr. OSCAR M. SCHLOSS, in closing the discussion, said that a cutaneous reaction was not always obtained in these cases. He was at present observing two cases of idiosyncrasy to eggs, manifested by gastrointestinal disturbances, in which there was no cutaneous reaction. In one case of hypersusceptibility to pork a cutaneous test was negative. A subcutaneous injection of pig's blood serum, however, gave rise to both local and general reaction. It was possible that the spontaneous recovery cited by Dr. Kerley was due to immunity produced by taking small amounts of the active substance as an ingredient of other foods. So far as was known at present anaphylaxis was due essentially to protein substances; whether the drug idiosyncrasy was dependent on the same or on a closely related condition was a subject for investigation.

Albumin Milk; Its Value and Indications in the Treatment of the Diarrheas of Children.—DR. HENRY HEIMAN read this paper, in which he gave the results of his experience with the "Eiweiss Milch" of Finkelstein. He said that the time-honored method of treating the diarrheas of infancy by catharsis, starvation, and the use of astringents in some instances brought about such a marked reduction in the resistance of the child that it readily succumbed to any of the numerous secondary infections to which it was exposed. The urgent need of a mode of treatment that conserved the strength of the patient and at the same time ameliorated the gastrointestinal symptoms had led the profession to hope that in the method of Finkelstein and Meyer this double need would be met. The studies of these investigators on the alimentary factors concerned in the production of intestinal fermentation showed the predominant rôle played by the carbohydrates and the salts. Intestinal fermentation was diminished by the removal or decrease of one or both of these elements. Further study demonstrated the fact that casein had a pronounced antagonistic action upon carbohydrate fermentation in the intestines. It was shown that if casein was present larger amounts of carbohydrates could be given without producing fermentation. These observations led Finkelstein and Meyer to prepare the mixture which they had called "Eiweiss Milch," consisting of casein and buttermilk. The chemical analysis of the food was as follows:

	Eiweiss milch.	Cow's milk.
Proteins	3.00	3.00
Fats	2.50	3.50
Carbohydrates	1.50	4.50
Ash	0.50	0.70

A liter of Eiweiss milk contained 370 calories. The results of the treatment of 150 cases of dyspepsia, decomposition, intoxication, and various parenteric infections were so successful that many of the German clinics adopted this treatment. The writer first used the Eiweiss milk in the latter part of the summer of 1910 and continued his observations during the entire summer of 1911. All patients admitted to the Children's Service of Mount Sinai Hospital suffering from diarrhea were given albumin milk for a period of from three to fourteen days. From this it was evident that the data obtained were derived from unselected cases. The original directions for the preparation of this milk were followed. A tablespoonful of Simon's essence of rennet (or two tablets of rennet) were added to one liter of milk, which was then placed in a water bath at 42 C. for one-half hour. It was then filtered slowly through cheesecloth by gravity without pressure for one hour. The coagulum was then washed twice in half a liter of water through a fine sieve and forced through by means of a wooden club. Then half a liter of buttermilk was added. It was found that by placing the cheesecloth in the sieve the particles of casein were more readily and uniformly forced through. A one-grain tablet of saccharin was added to the liter of milk; with this addition no difficulty was found in administering the mixture to children of any age. In general the quantity of albumin milk given corresponded to that of the usual feeding mixture prescribed for the respective age. The caloric value of the albumin milk being about one-half that of undiluted whole milk, the caloric needs of the child could be covered almost as readily by the albumin milk as by the customary diluted milk mixtures.

Finkelstein and Meyer now advised the use of carbohydrates in the form of malt soup or Liebig's extract of malt as soon as the quantity of milk ingested represented one-tenth of the body weight, even though the stools had not become entirely normal. In their series of cases malt was added to the albumin milk from the second to the eleventh day when proper gain in weight did not appear. The albumin milk feeding was continued from two to fourteen days. Most of the German observers had continued the use of the milk from four to six weeks; but, the service of the Mount Sinai Hospital being an acute one, it was found impossible to continue it for such a length of time. In no case did a relapse occur after the cessation of the albumin milk feeding. The usual procedure was to administer in the severe cases weak tea for from two to six hours before the albumin milk feeding was begun. No castor oil or laxative was given. In the less severe cases the milk was used from the beginning. It was stopped as soon as the stools became normal. Opium preparations and astringents were seldom employed, though stimulants such as caffein, camphor, and subcutaneous infusions were given. A change in the character of the stool took place in most cases in from two to five days. In nine cases mostly of the severe type the change did not take place within five days, though ultimate improvement did take place. In over one-half of the severe cases improvement in the general condition was perceptible in from two to five days. In some instances the change for the better was very striking. While albumin milk did not ordinarily produce a gain in weight unless carbohydrates were added, in most cases it checked the marked losses sustained by the patient under ordinary treatment. In the series of cases under discussion quite a number of patients showed a gain of from four to six ounces during the period of albumin milk feeding. Loss of weight was also recorded, but in only two cases was it more than one-half a pound. There were nine deaths in this series of forty-two cases, twenty of which belonged to a very severe type of the disease. This was a mortality of 21 per cent. Excluding four cases in which the albumin milk was given for three days or less, owing to the fact that the children were admitted to the hospital in practically moribund condition, they had left five deaths, or a mortality of 13 per cent. Of these forty-two cases sixteen were under 6 months of age. Seven of these belonged to the severe type of the disease, and of these three died. Very young children seemed to do as well as older ones on the albumin milk. From the generally favorable results obtained in this series of cases and from the bedside impressions the writer felt justified in concluding that a distinct advance had been made in the therapy of the diarrheas of children. The one indication for the use of albumin milk was diarrhea of no matter what origin or nature. It was especially indicated in those cases in which marked emaciation had taken place as a result of long withdrawal of food. In New York it had become possible to obtain the milk already prepared, but mothers and nurses should be instructed to shake the bottle thoroughly to prevent the casein from plugging the nipple.

Dr. John Lovett Morse of Boston said that some of the diarrheas of infancy were due to bacteria, some of which thrived on proteids, others on carbohydrates; some were due to chemical disturbances in the intestines; others to abnormalities in the blood. It was hard to see, therefore, how one and the same mixture could relieve the symptoms which were due to such different causes. Dr. Morse said that he had tried to find a rational explanation for the use of albumin milk. If the condition present in the infant was due to an organism which throve on carbohydrates it was easy to see that if the infant was fed proteids the growth of the organism would be discouraged. The addition of lactic acid to the food in the buttermilk would, however, tend to neutralize its action. If the condition was due to an organism which throve on proteids, the withdrawal of sugar and the addition of casein would, on the other hand, favor their growth. If the diarrhea was due to some lesion of the intestinal wall itself, probably caused by the fermentation of sugar, with symptoms due to the absorption of sugar and salts, it was plain that taking away the sugar and salts from the food would result in good. But lactic acid in the mixture would do harm by its irritant action on the intestinal wall. The rationale of this food, therefore, seemed to him very obscure. Dr. Morse said he had used this method of treatment in a small series of cases. The Walker Gordon Laboratory had prepared for him a mixture of cream, water, and precipitated casein, made according to Finkelstein and Meyer's methods, which contained very little lactose and salts, and which could be varied to suit the individual infant. In this way the addition of lactic acid in the buttermilk was avoided. When the acute symptoms were over and the stools had returned to the normal he added a preparation of dextrin maltose in order to get the required caloric value. This was a very useful method of feeding. The great difficulty, however, was to tell in just what class of cases this treatment would prove most useful. In a general way it might be said that it would be useful in cases in which there were numerous watery, light green stools which irritated the buttocks. These were the acute cases.

Dr. Robert Tucker Talbot said that he had seen sixty babies in a ward in which bacterial examinations of the stools had been made in most instances. They tried the modified food which was supposed to meet the biological needs of the bacteria. When they had a fermentative organism with which to deal they gave a food high in proteid, but low in carbohydrate because these organisms required carbohydrates in which to grow. They had all seen babies which had the symptoms of intestinal intoxication and where there were living bacilli in the blood, and how albumin milk could touch these organisms in the blood he could not see.

Dr. Linnaeus E. LaFetra said that if they used lactalbumin this should be gotten from the whey and not from a box. Some years ago Dr. Chapin had told him that it was more rational to add casein than lactalbumin to the milk since the casein was a nucleoalbumin and contained phosphorus and iron which were necessary for the development of the infant. He had begun the use of protein milk in the Babies' Hospital in 1910. The sixty-two infants treated had ordinary diarrheas with stools containing blood and mucus. In these stools the Shiga organism was found. These cases were all treated with the albumin milk. There were twenty-one cases of severe diarrhea among them, and these babies were placed upon the albumin milk even when they had fever and all the cases with the exception of three improved. Of these two died and the other was taken home. In the total series there were four deaths. They were given the protein milk from two to ten days and it was decided not to keep them on this food any longer unless they were gaining in weight. With the addition of albumin milk in these cases of severe diarrhea the loss of weight was less and the stools returned more quickly to normal than under any other method of treatment. All forms of diarrhea seemed to be very much benefited by the use of the albumin milk.

Dr. Charles Gilmore Kerley thought that in considering the results that Dr. Heiman had obtained with the use of albumin milk they should bear in mind the fact that the summer of 1911 had furnished a very low mortality in intestinal diseases in children. The cases that they had met with during the summer were of a mild

character. In his experience of twenty-four years with these cases he had never seen such a low mortality. The credit of this was due in a large measure to the efforts of the Board of Health and the organizations which had assisted them in their work. In the Babies' Hospital of New York the babies brought in were what were termed "dead ones." Many of them were cases of autointoxication. In Berlin they seldom met with such cases. Here they were talking of one type of cases, while in Berlin they were talking of another. There did not seem to be any common ground for comparison, as abroad they had no hot air and no humidity. This was not so, however, in Boston. With regard to giving lactalbumin in all forms of diarrheas accompanying gastric disturbances he disagreed entirely. This form of treatment might do well in children over 18 months or 2 years of age, but in children under 1 year it would not do at all. These young babies could not take lactalbumin. Dr. Kerley did not think the "Eiweiss Milch" was of general applicability; it should be used only in a selected type of cases; and when so used it gave excellent results. In properly selected cases the children took up this milk and digested it better than anything else that could be given. Dr. Kerley said that his experience with this milk during his earlier career had been somewhat unfortunate, but he now recognized that the reason was he did not understand its application.

Dr. Henry Dwight Chapin said he had used Finkelstein's method of feeding children with diarrheas for two years and he thought it had a restricted value in certain cases. He agreed with what Dr. Morse had stated, that diarrheas were due to many different causes, and that if a high protein was required it should be split up into such a form as could be easily assimilated; it was the form in which the proteid was given that rendered it digestible. He added sugar to casein milk in the form of maltose, as it was more quickly assimilated. Dr. Chapin believed that this method of feeding had a restricted value in certain types, and particularly in the dysenteric forms of diarrheas.

Dr. Henry Koplik thought that they should give Finkelstein and Meyer credit for working out according to their own ideas, a way to feed babies who were suffering from diarrhea. Finkelstein was right in stating that some of the younger babies would take the albumin milk readily, while others would not take it. This food was not always available in private practice. Finkelstein did not advocate the use of this milk in every case, and he did not see the cases of severe intoxication and decomposition that were seen in New York. Many of the cases admitted to the New York hospitals were marantic septic cases and it would be impossible to save them by any method of feeding. Dr. Koplik expressed himself as not especially impressed by this method of feeding, and said that he was not yet willing to relinquish the older methods which had proved of value in his practice. He had in several instances used the Eiweiss milch in newborn babies suffering from intestinal decomposition, but it did not seem to be sufficient to sustain the infants. There was no food ever yet invented, the speaker said, that would save all of a certain class of cases. It was not the food that cured, but the disease that killed these babies.

Dr. Henry Heiman, in closing the discussion, said that his cases were not selected. There were forty-two cases, mostly diarrhea of the catarrhal form, with blood and mucus in the stools, and there was no treatment that produced the desired results in such cases. He believed the disease was a self-limited one, like typhoid fever, lasting in the different cases from ten days up to as long as two or three weeks. He did not believe there was any food that would give the babies as many calories as the albumin milk.

Philadelphia Neurological Society

At a stated meeting held January 20 Dr. Milton K. Meyers presented a communication entitled "Epilepsy in Adult Life in Association with Thyroid Disease: Report of Six Cases, with Exhibition of the Patients." He cited a number of cases of both minor and major epilepsy in which there was obvious anatomical change in the thyroid gland, and he discussed the evidence bearing upon a possible interrelation between the two sets of conditions. Dr. Alfred Gordon presented "A Case of Juvenile Tabes." The patient was a girl 18 years old, who had presented symptoms of her condition from the age of 13. She presented inequality of the pupils with sluggish reaction to light, normal optic discs, lightning pains, and girdle-sensation, good station and gait, preserved coordination in the upper extremities, normal reflexes, together with a positive Wassermann reaction. Dr. William B. Cadwalader exhibited "A Case of Unilateral Fifth-Nerve Palsy of Syphilitic Origin." The patient was a woman, about 35 years old, who presented twitching of the right side of the face with impaired sensation in the distribution of the fifth nerve and a positive Wassermann reaction. Marked improvement took place under treatment with arsenobenzol. The opinion was expressed that the disorder was due to syphilitic infiltration of the root of the fifth nerve near its origin from the pons. Dr. Cadwalader exhibited also "A Case of Bilateral Seventh-Nerve Palsy of Syphilitic Origin." The patient was a man, about 35 years old, employed as a stationary engineer. Following exposure to cold while overheated he found difficulty in performing movements with one side of the face and on the following day similar difficulty was experienced on the opposite side of the face. Also there was marked occipital pain. The patient presented a strange expressionless appearance, with the lower jaw depressed and both eyes kept open. Speech was scarcely intelligible and the lips could not be pursed, as in whistling. While under observation girdle-pains appeared and the knee-jerks were abolished. A positive Wassermann reaction was obtained and under active treatment with mercurials and arsenobenzol the pains disappeared, the facial palsy improved greatly, and the knee-jerks returned. While it cannot be definitely maintained that the paralysis of the muscles supplied by the seventh nerve on each side was due to syphilitic infiltration of the nerves it is not impossible this acted at least as a predisposing factor and that the exposure to cold while overheated acted as a final exciting cause. Dr. Alfred Reginald Allen read the "The Presidential Address," in which he considered the views of Janet, Freud, and Babinski with respect to hysteria and its treatment.

The following officers were elected for the ensuing year: *President*, Dr. J. H. D. Rhein; *Vice-Presidents*, Drs. A. A. Eshner and S. D. Ingham; *Secretary*, Dr. George Price; *Treasurer*, Dr. S. W. Ludlum.

The Pancreatic Syndromes in Tuberculosis.—M. Lœper states that tuberculosis is frequently accompanied either by pancreatic insufficiency or by pancreatic hypersecretion. The most frequent sign of the former is diarrhea. The latter is not infrequent at the beginning of tuberculosis. Tuberculosis may lead either to sclerosis, degeneration, atrophy, or inflammation of the pancreas, or to hyperplastic reactions, which are well marked not only in the lobules but also in the islets of Langerhans. From a practical point of view the author recommends what he calls "the intensive pancreatization" of tuberculous patients and states that in many cases of tuberculosis in which sclerotic or degenerative changes of the pancreas have followed hypersecretion the stimulation of the pancreatic secretion has given him very satisfactory results.—*Progrès Médical.*

Medicolegal Notes.

Malpractice—Sufficiency of Evidence to Go to Jury.—In an action against a physician and surgeon for malpractice the principal allegation was that he had negligently left a large amount of cloth and gauze in the wound in the plaintiff's abdomen, which had remained there from November, 1906, to October, 1908, when it was removed by other physicians and surgeons. The defendant contended that there was no direct testimony of the leaving of the gauze in the wound at the 1906 operation, and if it was found as testified to by the doctors who performed the 1908 operation, it must have been placed there at a prior operation made in 1905. He swore that he did not make an incision entirely through the abdominal wall, but merely penetrated the aponeurosis of the recti muscles and that the operation was outside of the peritoneal cavity. And in this he was corroborated by the nurse. He also swore that neither at the 1905 nor the 1906 operations did he use any packing, but he did use a dressing and sponging. The plaintiff conceded that there was no direct testimony showing that the defendant left gauze in her abdomen at the 1906 operation, but contended that the circumstantial evidence that such was the fact was well-nigh conclusive. She maintained that in the nature of the case direct proof could not be furnished. She was under the influence of an anesthetic at the time of the operation, and the only other persons present were defendant, his wife and the nurse.

Three operations were performed on the plaintiff, in 1905, in November, 1906, and September, 1908. Then the gauze was removed in October, 1909. The question was, when was it placed in the wound? The nurse positively testified that there were no sponges left in the plaintiff's abdomen at the 1905 operation. She was also present at the 1906 operation and counted the sponges before the operation but not afterwards. That operation, according to the defendant's testimony, was a slight external operation for the purpose of opening an abscess. He said he packed some gauze into the opening of the abscess at that time but that he did not put it in deep. It was his theory that that was the gauze which was removed in October, 1908. The plaintiff, however, testified that shortly after the defendant placed the gauze in the abscess it pained and hurt her, and she removed it herself. This was corroborated by the doctors in the October, 1908, operation, who swore that the gauze which they removed was in the inside of the abdominal wall. Another doctor, a witness for the defense, gave it as his opinion that the gauze must have been imbedded at the place where it was found, and that witness also stated that it is possible for gauze left between the peritoneum and the muscles to remain, not only three, but fifteen years, but it could not remain if in a bad condition. The court considered that there was sufficient evidence to require a submission to the jury of the issue as to whether the gauze removed in October, 1908, was left by the defendant in the plaintiff's abdomen at the operation in November, 1906, or not. It therefore overruled the defendant's motion for a directed verdict.

Judgment for the plaintiff was, however, reversed and a new trial ordered for the reason that the trial judge in charging the jury instructed them to disregard the statements of counsel and try the matter from the evidence introduced and the instructions of the court—Zilke vs. Johnson, North Dakota Supreme Court, 132 S. W. 640.

Degree of Care Required of Physicians.—In an action for malpractice a verdict for the plaintiff was set aside on account of failure to give a requested instruction which would have limited the degree of skill required of the defendants to that possessed by physicians practising in similar localities. It was said by the court that the degree of skill which a country doctor can reasonably be assumed to possess in performing difficult surgical operations must, as a general rule, be measured and determined by a due consideration of the limited opportunities afforded in the same or similar communities, and not by the greater and dissimilar opportunities existing in larger and different communities. It would be unjust to hold him to a degree of professional ability which his environment prevents him from possessing. On the other hand, it would be equally unjust to the plaintiff in a malpractice case to permit the jury to measure the defendant's skill by the average of professional ability found to exist in other communities affording less opportunity for practice in a given medical line than the defendant's locality affords. In the former case the standard would be too high; in the latter it would be too low. In neither case would it work out substantial justice. An instruction that the defendant was bound to possess the learning, skill and experience of the average physician and surgeon in the profession of medicine was held objectionable because it failed to restrict the jury to any locality in the attempt to find the average skill of the medical profession in surgery. It was impracticable because of the difficulty of determining the average skill of the profession as a body in the treatment of a given case. Different schools of medicine often employing radically different methods of treating the same disease, the practice followed in one school would often be strong evidence of negligence, if resorted to by a member of another school. The implied agreement of the surgeon is that his surgical knowledge and experience is at least equal to that of the average surgeon practising in the same or similar localities, not to that of the average of surgeons practising in dissimilar localities. To restrict the locality doctrine to the same locality might, it was said, restrict the inquiry to a too narrow territory. The defendant's actual practice might be limited to a single town where no other physician practised, and in such a case necessarily no comparison could be made. The court could not take judicial notice as to whether the average skill of the medical profession as a body was higher or lower than that of physicians practising in localities similar to that where the defendant practised, and declare it to be one way or the other; therefore, it could not say that the charge that the degree of skill required of a country physician is such as is ordinarily possessed by the professor was not erroneous, as imposing too high a standard of medical skill as applied to the defendant.—McBride *v.* Huckins, New Hampshire Supreme Court, 81 Atl. 528.

Expert Evidence as to Cause of Condition.—In an action for injuries sustained by a railroad passenger in a collision the facts of the collision and the injuries complained of were stated in a hypothetical question to a medical expert witness and then he was asked what he would say was the cause of the passage of blood from the bowels and the injured person's sprained back. It was held that the question was objectionable as calling for a conclusion of the witness in a matter directly in issue, and not merely the expression of an opinion. The fact that the witness on cross-examination stated that if the plaintiff did not pass blood from his bowels when he was in the hospital, but some weeks after, he would not attribute the cause of his condition to his injury did not neutralize the effect of the former question and answer, as it was based upon a different state of facts. The object in such cases, it was held, is not to show, by expert medical evidence, a condition, but to account for the condition; that is, to ascertain the cause that produced the condition.—Holzen *v.* Missouri Pac. Ry. Co. (Mo.), 140 S. W. 767.

Privileged Communications.—A physician in a railroad company's hospital who attends a person brought to the hospital for treatment for injuries received in a collision while a passenger of the company sustains to the person injured the confidential relation of doctor and patient and is incompetent to testify against the objection of the injured person.—Holtzen *v.* Missouri Pac. Ry. Co. (Mo.), 140 S. W. 767.

Nonexpert Evidence as to Insanity.—In a Kentucky homicide case where the defense was insanity the medical expert witnesses for the accused said that he was a paranoiac; those for the commonwealth, that he was not. It was held that paranoia was not so peculiar a disease that no one but a medical expert who had made it a study could understand or portray it, and that non-experts should not be excluded from testifying on that account. Assuming that the accused was a paranoiac, non-experts, it was held, were equally as competent to give opinion evidence as non-experts would be in any other ordinary case of insanity. It was also said that when a non-expert witness is allowed to express an opinion that the accused is of sound mind there seems no reason why he should not also be permitted to express an opinion that he knows right from wrong. One opinion does not require more knowledge than the other, nor is one more than the other a usurpation of the functions of the jury.—Banks *v.* Commonwealth, Kentucky Court of Appeals, 141 S. W. 380.

In a Texas homicide case the rule was stated that non-expert witnesses, when they are shown to have had a sufficient knowledge of the accused for a sufficient length of time, and came in contact with him, and have had conversations and business relations with him for any considerable period of time, based solely on their own knowledge and observation, can express an opinion as to the sanity or insanity of the accused.—Jordan *v.* State, Texas Court of Criminal Appeals, 141 S. W. 786.

Basis of Physician's Opinion as to Cause of Injury.—

On a trial for personal injuries caused by being ejected from a trolley car, a physician called as a witness for the plaintiff was asked whether, having heard all the testimony of the plaintiff, he could, from that testimony and from the medical examination that he made of the plaintiff, form an opinion as to what caused the conditions that he found. It was held that there was no error in allowing him to state his opinion over the objection that no foundation was laid for the question, the objection being too general.—William *v.* St. Paul City Ry. Co., Minnesota Supreme Court, 133 N. W. 465.

Basis of Physician's Opinion.—In a trial for murder there were no eyewitnesses except the accused to the killing. He testified to such a state of facts as from his standpoint tended to show that he was acting in self-defense. Two shots were fired and a very material fact in the case was whether the first shot entered under the arm of the deceased or not. It was held that it was improper to permit a physician to testify as an expert to an opinion that the first shot was the one that entered under the arm, and that the wound on the arm was not inflicted by the same shot. It was for him to detail the character, location, etc., of the wounds and for the jury to determine this material fact.—Powdrill *v.* State, Texas Court of Criminal Appeals, 138 S. W. 114.

County's Liability for Disinfecting Buildings.—Where a county is liable for the expense of disinfecting buildings in which contagious diseases have existed persons who have formerly disinfected buildings can, in an action by a health officer against the county for the value of his services, testify as to the charges made by them for their work, they stating what they had done, the material used, its value, and the time consumed, though they were not physicians or experts in disinfecting. The county was not liable for more than the reasonable value of such services, if they were such as could be equally well rendered by non-experts. The approval of the bill for such services by the local board of health was only prima facie evidence of their value. If the board ratified the services, the existence of a prior contract for them was immaterial.—Sawyer *v.* Wapello County, Iowa Supreme Court, 133 N. W. 104.

New Instruments.

A NEEDLE HOLDER FOR THE INTRAVENOUS ADMINISTRATION OF SALVARSAN.

By HUBERT V. GUILE, M.D.,

NEW YORK,

ADJ. ASST. VSSITING PHYSICIAN, BELLEVUE HOSPITAL.

THE contrivance here described has been devised for the purpose of dispensing with the necessity of holding the needle by hand during the intravenous administration of 606. The use of this apparatus simplifies the procedure to a considerable degree and does away with a rather tedious and unnecessary task. In addition, the needle is held far more steadily than is the case when held by hand, and provided no traction is exerted upon the tubing, there is far less danger of the needle being withdrawn accidentally from the vein during the operation.

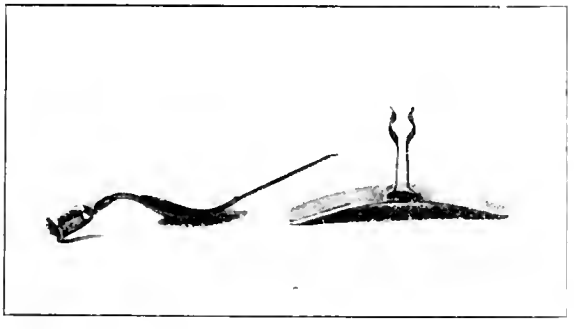

Fig. 1.—Needle and support.

The device consists of a thin nickeled brass plate, 5 cm. in length by 2 cm. in width. The under surface is slightly concave in order to conform to the convexity of the forearm. Upon the upper surface and anterior border of the plate there is attached a small spring clip which may be rotated to any desired angle by means of a swivel joint. The spring clip is 2 cm. in height, which corresponds to the distance to which the hilt of the Schreiber needle rises above the surface of the skin when the point is inserted in the vein.

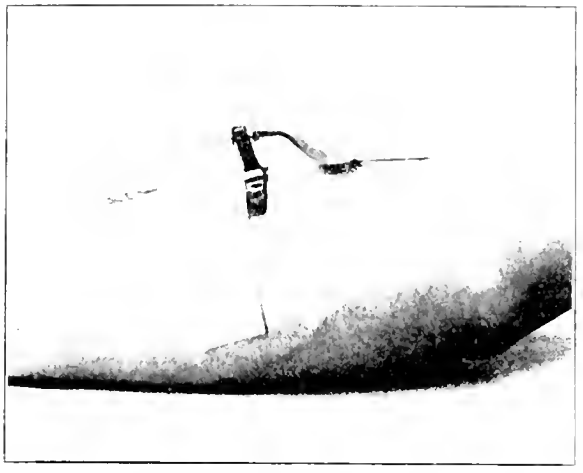

Fig. 2.—Needle held in the vein.

The use of the needle holder is as follows: All preparations for intravenous administration of salvarsan having been completed, the hilt of the needle is placed in the spring clip of the holder and the needle is thrust into the vein. As soon as we are sure that the point is well within the lumen of the vessel, as is shown by the backward flow of blood through the needle, the holder is securely strapped to the forearm by means of a strip of adhesive plaster about 13 cm. in length by 2 cm. in width. This passes over the metal base of the holder and firmly binds it to the forearm until the operation is completed.

The illustrations will explain the use of the apparatus far more clearly than words can do.

In closing, a word of caution should be given. The rubber tubing leading from the salvarsan container to the needle should be sufficiently long to prevent any possibility of traction being exerted upon the needle holder; for in this manner it is possible to pull the needle out of the vein, owing to the sliding of the skin upon the deeper structures of the arm.

200 WEST EIGHTY-SIXTH STREET.

The Serum Treatment of Cerebrospinal Meningitis.—A. Papapanagiotu describes his results in the treatment of fourteen cases of cerebrospinal meningitis in private practice with the anti-meningococcus serum. The patients, from the ages of eight months to ten years, all recovered. It is unusual for children under one year of age to recover from this disease, hence the results are all the more astonishing. The cases all occurred in the winter months and all were treated at their homes. The author believes that the patients themselves as soon as they are isolated become comparatively harmless, since no two cases occurred in the same family. The attendants of the patient are apt to harbor the meningococci in the nasopharynx and to become dangerous carriers of the disease. The injections of the serum should be given as early as possible in order to get the best results, and may need to be repeated three to four times. The amount given should be 30 c.c. after the age of two years and 10 to 20 c.c. in younger children. The fever at once subsides and all the general symptoms are relieved. The best evidence of the improvement is seen in the fact that the cerebrospinal fluid beomes less turbid.—*Archives de Médecine des Enfants.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended February 23, 1912.

THE OCCUPATIONAL NEUROSES.*

A CLINICAL STUDY OF ONE HUNDRED CASES.

By CHARLES L. DANA, M.D.,

NEW YORK.

THE nervous troubles which affect people engaged in skilled manual occupations, and are due to the neuromuscular work itself, are not as numerous or serious as those due to poisons and poisonous fumes and dust. The number of cases of lead poisoning, for example, is probably greater in the ordinary dispensary than the number of cases of cramps, and neuralgias, and neuritis which are met with in these places. Nevertheless, they are matters of distinct importance, for with each new form of mechanical invention which calls for skilled manual labor some new occupational neurosis arises. It is worth while, therefore, to pay some attention to this class of disorders.

The forms of trouble which we meet with in manual workers may be grouped under four headings:

1. Occupational pains and symptomatic cramps.
2. Occupational neuritis and atrophy.
3. The acroparesthesias.
4. The true occupational or professional cramps.

The distribution of these disorders is shown in the following table:

Median neuritis.....	10	Acroparesthesia (hand)	8
Ulnar neuritis.....	10	Symptomatic cramps.	6
Musculospiral neuritis	2	Genuine occupational cramps	23
Circumflex neuritis.	2	Sciatic leg pains....	3
Peroneal neuritis...	2	Occupational torticollis	2
Atrophy (hand and arm)	9		
Brachialgia	20	Total.....	97

These four types of disorders are not always sharply distinguishable, and often a person may suffer from two or more of these troubles at the same time. Thus neuritis and atrophy would be accompanied by paresthesias and pain. In the occupational pains which affect the arm so severely there is probably often a certain amount of neuritis and often a certain amount of symptomatic cramp and weakness.

The very wide range of skilled labor which is affected by these disorders is shown in the tables which I have here.

It will be remembered that I am not including lead cases.

*Read at a meeting of the New York Academy of Medicine, January 4, 1912.

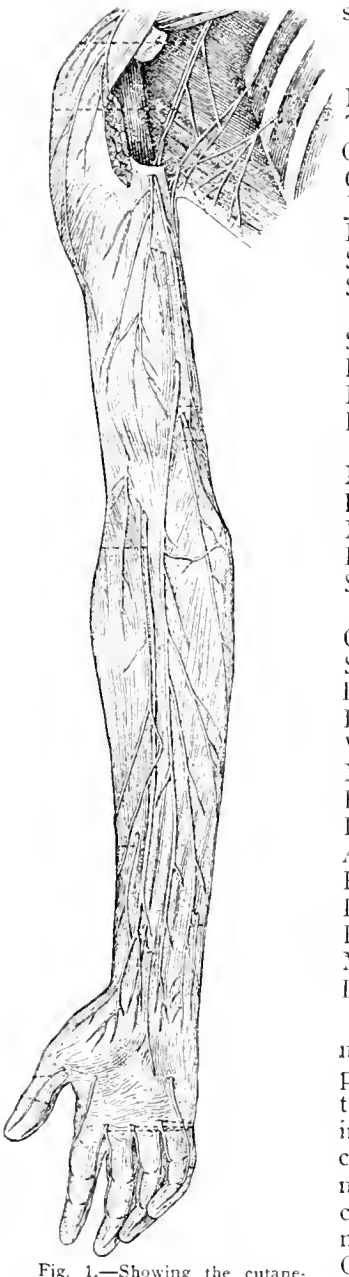

Fig. 1.—Showing the cutaneous nerves of the arm, front surface.

SOME OCCUPATIONS IN OCCUPATIONAL NEUROSES.

Pressers and ironers
Tailors
Carpenters
Cigarmakers
Jewelers
Barbers
Seamstresses
Sewing machine operators
Stone cutters
Elevator boys
Paper box makers
Lithographers (stone polishers)
Miniature painters
Lathers
Machinists
Bookkeepers
Stenographers and typewriters
Clerks
Surgeons
Laryngologists
Dentists
Violinists
Milkers
Pianists
Flute players
Auctioneers
Pavers
Housewives
Bookbinders
Modelers
Drummers

This does not by any means represent a complete list, but it covers the forms of occupation in about 100 consecutive cases of occupational neuroses which have come under observation, mostly in the Cornell Clinic for Nervous Diseases.

It will be seen that the occupations which are most frequently affected are those in which the higher class of skilled labor or craftsmanship, namely, that of the writers, telegraphers, stenographers and typewriters, musicians, and artists is employed.

Among the relatively unskilled operators it is the pressers and ironers and tailors who suffer most from occupational diseases. Indeed, after them there is in the clinics of this city a very sharp drop to the other kinds of skilled employment.

A study of the nature of the troubles shows that it is the hand and the nerves of the arm which are by far the most frequently affected. The hand with its delicate supply of nerves and muscles is one of the most complete and perfect works of creative skill, and it is not surprising that so delicate an organ should be injured by the strains, the injuries, and the overwork put upon it.

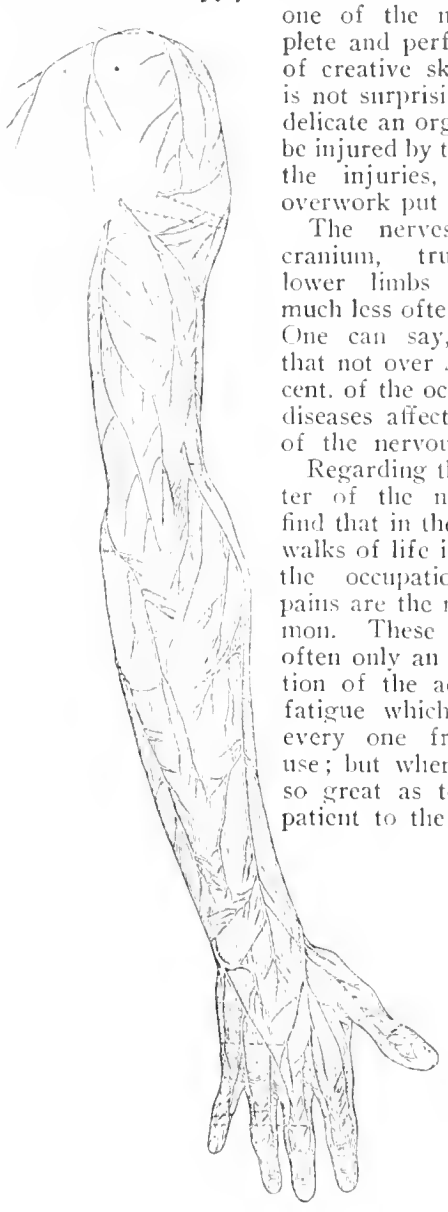

Fig. 2.—Showing the cutaneous nerves of the back of the arm.

The nerves of the cranium, trunk, and lower limbs are very much less often affected. One can say, perhaps, that not over 4 or 5 per cent. of the occupational diseases affect this part of the nervous system.

Regarding the character of the neuroses I find that in the ordinary walks of life in this city the occupational arm pains are the most common. These pains are often only an exaggeration of the aching and fatigue which come to every one from overuse; but when they are so great as to call the patient to the physician it means that the aching of the arm has become chronic—that the arm is weak and tender, and that the patient is unable to continue work for more than a short time without exhausting its power or causing so much pain that he has to cease. Very often the arm pains are accompanied with points of tenderness and with some swelling, sensations of numbness and prickling; so that a certain amount of neuritic irritation is no doubt present.

In most cases, however, the pains are not of very serious degree, except when some work is undertaken; then the arm becomes weak and very painful, and useless. It is the ironers and laundresses and pressers and tailors who come to our Clinic most often with this complaint. Violinists and professional pianists also suffer a great deal.

While occupational cramps such as those which affect writers and stenographers, and so on, are nearly as common as the brachialgias, they occur in a different class of persons, and are not seen so often relatively in the dispensary clinics.

An actual neuritis of the nerves of the arm occurs nearly as often as occupational neuralgia. This neuritis affects the ulnar nerve and the median nerve in about the same proportion. Rarely it affects both nerves at the same time. The condition is brought about by the pressure and pounding of the parts involved in the particular kind of work that is done.

We find neuritis among ironers and pressers, cobblers, jewelers, masons, and among all craftsmen who use tools that they hold tightly in the hand and with which they exert hard pressure.

Occasionally neuritis leads to distinct and extreme atrophy of the intrinsic muscles of the hand, either of the thenar or hyperthenar eminence, or both. In a few cases in which there are predisposing influences this occupational atrophy passes on to a progressive muscular atrophy.

Dr. Ramsay Hunt has described a distinct form of occupational atrophy which involves the deep plantar branch of the ulnar nerve. This deep branch is a purely motor nerve, and is the one which supplies all the muscles of the hand of the ulnar distribution. Pressure is brought to bear in such a way that this deep branch is practically crushed against the bone beneath; the terminal filaments degenerate and the muscles atrophy, without any sensory disturbances.

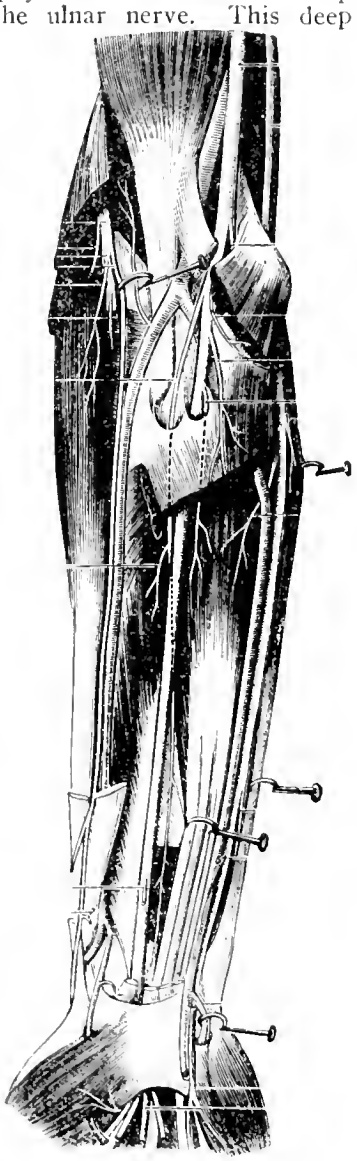

Fig. 3.—The deep nerves of the forearm, anterior surface.

The acroparesthesias which occur in occupational diseases are symptoms of irritation and pressure upon the terminal filaments of the sensory and vasomotor nerves of the fingers and hand. The patient suffers from sensations of numbness, and tingling, of burning, and redness and swelling, and sometimes of pain; but there is not usually any great amount of motor disturbance.

These occupational paresthesias occur in cigar-makers and in almost any form of manual occupation in which the fingers are subjected to continual irritation and pressure. They are most commonly seen, however, in the hands of housewives who have to do a great deal of washing, and who are subjected both to trauma and to the influences of moisture and cold.

I shall say nothing about the true occupational cramps because it is a subject that is familiar to all, and one to which I can contribute nothing new. It is to some a question as to whether occupational

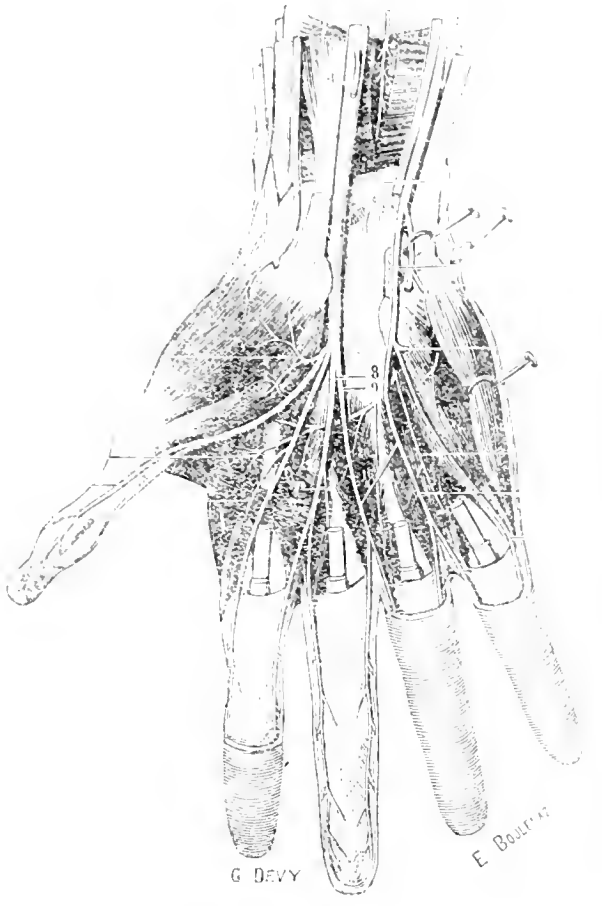

Fig. 4.—The median and ulnar nerves of the hand, deep branches.

cramps are central or peripheral—that is to say, whether they are neuroses of the type of the tics, or whether they are due to some grade of neuritis. My experience is that the true types are all of central origin, but there are often symptomatic cramps occurring in the brachialgias, or aching arms, and often some symptomatic cramps are associated with neuritis.

In comparatively rare cases the musculospiral and circumflex and long thoracic nerves are affected and we get paralysis of the shoulder and of the serratus. Such palsies occur in porters and in persons who carry heavy weights upon their shoulders.

There is no doubt that occupations have something to do with the injury of certain of the cranial nerves, notably those connected with the motor functions of the eyes, as in Miner's nystagmus; those connected with producing blepharospasms and with certain other activities of the facial nerves. Thus an occupational cramp of the facial nerve occurs in flute players and in other wind musicians, and there has even been recorded a case of autioneer's cramp (Zenner).

Some of the cases of torticollis are undoubtedly of occupational origin. I have the record of the case of a bookbinder who suffered from torticollis on account of the steady, constant, and rhythmical movements of the neck, which she had to make in doing her work.

Dressmakers, dentists, cigarmakers, and probably many other kinds of workers suffer from occupational pains of the neck, side and back.

As I have said, there are few occupational neuroses of the lower limbs. I have the record of the case of a pedaler who worked a pedal for ten hours every day, using one leg and foot, and finally developing in it occupational pains. Similar cases have been reported. In Germany there is a peculiar occupational neuritis and cramp occurring in potatoe diggers and in persons engaged in raising vegetables who are obliged to squat or get down on their knees in their labor. The tendon of the biceps femoris when the leg is flexed presses the peroneal nerve against the head of the fibula, causing pain and paralysis in this nerve. Sometimes tailors suffer in the same way.

The question of prevention is of course the one that is the most important in the present discussion of this subject. It seems to me that articles on "industrial efficiency" might be written that would cover this point, for there are hardly any of the occupational disorders of the arm and hand of which I speak that could not be prevented by a wise and more careful application of the labor. The cases of motor and ulnar neuritis, for example, are almost always due to persistent and careless pressure which injures the nerves because the instrument used is not held correctly or because the handle is not properly protected by some kind of cushion.

Fig. 5.—The deep branches of the radial nerve, posterior surface of the forearm.

Extreme cleanliness would prevent a great many of the paresthesias. Occasional periods of rest with a better direction of effort would prevent a great many cases of arm pains.

Pamphlets in which descriptions of the results that may occur to those engaged in ironing, pressing, or cigarmaking, in washing, in the handling of tools, etc., would, I think, be of distinct help. "Why Have Crippled Hands?" or "Why Have Aching Arms?" such should be the catching titles.

The disorders of which I have been speaking particularly attack those people who earn their living by the skilful use of the hand, the craftsmen of various kinds, and this is a particular and most important type of calling whose interests should especially appeal to us. And I would like again to impress upon the laity and the physician a theme which is rather dear to me, viz. that of the delicacy and value of the hand as an instrument of education as well as of labor and precision.

The use of the hand moves the industries, enriches and builds up the State, creates art, and through its deftness and precision is the essential instrument in evolving beauty and ministering to

Fig. 6.—The nerves of the back of the hand.

the esthetic; the skilful use of the hand also educates the user; a manual craftsman is a sounder and saner man because of his labor; and the training of the hand is one of the important factors in the education of the child.

The great mass of industrialists work with machinery or simply dig and delve, fetch and carry. They have no occupational neuroses except such as are due to accidents and bad living. This kind of worker is perhaps crowding out the craftsman, but we need the latter immensely in our civilization and we and he ought to do all that is possible to protect him from the neuroses and other diseases that befall him in his calling. Let us protect the laborer, but let us especially cherish the craftsman. He was the lasting glory of the Middle Ages and he is still an enormous help to the civilization of to-day.

I have thought that this paper might be used as a basis for further investigation by those, not necessarily physicians, who are interested in industrial diseases. Hence I am adding six anatomical illustrations showing and emphasizing the nervous supply of the arm and hand.

A bibliography of occupational neuroses may be found in E. Remak's article on occupational neuroses in Nothnagel's "Specielle Pathologie u. Therapie." This brings the subject down to the year 1898.

In this bibliography only two American writers are quoted.

A more recent bibliography is given by Dr. J. Ramsay Hunt in his article on Occupation Atrophies in the Neurological Report of Cornell University College, Vol. 3, 1911.

HYSTERIA AND PSYCHOTHERAPY.

By EUGENE D. BONDURANT, M.D.,

MOBILE, ALA.

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE UNIVERSITY OF ALABAMA.

No satisfactory definition of hysteria can, at the present moment, be constructed, because there is no general agreement as to what psychoneurotic disturbances shall be included under the term and what excluded therefrom. Many physicians, including those who have little patience with nervous diseases in general and none at all with hysteria in particular, and who therefore try to think about it as little as possible, regard hysteria in a vague way as synonymous and coextensive with neurodegeneracy and as always tinged with exaggeration, pretence, and simulation. Babinski, at the other extreme, believes that hysteria is morbid suggestibility, and its symptoms the direct result of suggestion and of that alone. One may choose either of these views. I believe that Babinski's conception of hysteria as morbid suggestibility is concise, clean cut, and in at least approximate accord with demonstrated fact. None the less, the patient suffering from hysteria manifests symptoms which are not due to suggestion. These symptoms, which are the outward visible signs of the underlying neurodegeneracy, have to be admitted to a place in the clinical picture of hysteria because they are there whether we admit them or not. Babinski, recognizing the practical difficulty of trimming down the hysteria symptom complex to fit his restricted definition, proposes to drop the term hysteria and to call the morbid suggestibility syndrome "pithiatism." The view which I adopt in this paper is that hysteria is a degenerative psychoneurosis, whose characteristic symptoms are due to suggestion.

The phenomena of hysteria become more intelligible if it be borne in mind that they result from a mingling in varying proportions of the etiological factors of neurodegeneracy and morbid suggestibility. An understanding of what is meant by "degeneracy" and by "morbid suggestibility" is essential. By degeneracy is meant failure to attain in development the racial standard of anatomical structure and physiological function. The condition is one of inherited and developmental defect. The degenerate represents a reversionary variation from the racial type. The innumerable nervous symptoms of degeneracy may be grouped as functional weaknesses, perversions, and defects. Among the neurodegenerate perversions of function, heightened suggestibility is prominent, and for our present purpose, most important. Now suggestibility is inherent in the human mind. The normal man is suggestible—influenced by suggestion—deriving many of his beliefs, opinions, sentiments, and feelings from this source. Were we not suggestible, *i.e.* influenced by precept and example, we would be less readily educatable. The function or quality of suggestibility underlies all emotion, and in normal proportion and under normal restraint is an intellectual motive power of undoubted value to the man leading a normal existence in intimate association with and dependence upon his fellow man. When abnormally developed, however, or when improperly regulated and controlled by the reasoning mechanism suggestibility becomes a pro-

*Read before the Mobile County Medical Society, May 18, 1911.

lific source of error and defect in judgment, and of mental weakness, constitutes an important factor in what we denominate "nervous instability," and contributes largely to the subjective symptomatology of disease.

The extensive and vaguely delimited group of morbid conditions which we include under the term "psychoneuroses" have their common etiologic basis in degeneracy, and are collectively characterized by symptoms of generalized nervous weakness, with, in many instances, special or more conspicuous defect in some particular function, or in a small related group of functions. When morbid suggestibility is shown, and the symptoms are such as are produced by suggestion, the condition may properly be called hysteria. The morbid suggestibility group of symptoms, as has already been pointed out, is rarely met with pure and uncontaminated, usually occurring in association with other neurodegenerate manifestations. Conversely, in almost all psychoneurotic disease—in almost all disease of any kind, in fact—we find some evidences of heightened suggestibility, which means that the stress of sickness, with its malnutrition, toxemia, and disordered metabolism renders us all more suggestible, more unstable, unbalances us, weakens us, makes us "degenerate," as it makes us childish. The predisposing factor, then, in hysteria is neurotic heredity. The contributory somatic factors are malnutrition, toxemia, fatigue, and allied states. The determining factor is suggestion.

The cure of this, as of any other morbid condition, means correction of structural and functional defects. Enduring cure is conditioned upon removal of the cause. In this instance the basic cause can be removed only by stopping the reproduction of the unfit. We will have ample time to discuss this prophylactic measure before we are able to put it into effect, so we may safely leave this phase of the question for future consideration, turning our attention to the matters of present and practicable moment.

The removal of the contributory etiologic factors included under the general or local associated states of bodily disease manifestly fall within the province of the physician, and possess a present if somewhat overrated importance. They are, in practice, the points against which our chief conscious attack is directed. Recognizing the intimate relation between health and stability, between disease and degeneracy, remembering that our inherited degeneracy is but an expression of ancestral ill-health; that our previously latent symptoms of neurodegeneracy are unmasked by the associated disease, we doctors have concentrated our attention upon these associated morbid states. All of us are apt to attribute hysterical symptoms to some coexistent bodily ill, especially to that class of diseases in which we happen to feel most interest. And all of us attempt to cure hysteria by the application of that therapeutic procedure with which we are most familiar. The gynecologist attacks the problem by removing one or two ovaries, or by repairing the uterus; the surgeon by cutting out the appendix vermiformis, anchoring a loose kidney or resecting the large intestine; the ophthalmologist by correcting the eye strain; the gastroenterologist by washing out the stomach; the neurologist by rest cures, electrotherapy, and the other appurtenances of his trade. The doctor of the old school obtained equally favorable results by nauseous potions, counterirritation and venesection. Every one of these measures, and many more, meet with a certain degree of success, give a certain amount of relief from the symptoms which, at the time, the doctor and patient regard as most inviting attention. So we must acknowledge that there are about nine and sixty ways of treating hysteria, and that every single one of them is right, more or less, because they all contain the vivifying germ of suggestion.

And as to the very great therapeutic value of suggestion there is little room for difference of opinion. But on the other hand, remembering that the one determining factor in the causation of hysteria is suggestion; remembering that the specific hysterical symptoms are produced by and are a direct result of suggestion, the danger incident to the employment of any procedure possessing a powerful suggestive character must become evident. The surgical operation, the impressive or spectacular mode of medical or special treatment, sometimes removes the hysteroid local or general symptom only to replace it by some other, which disastrous outcome is likewise favored by the unhealthy introspection, and the morbid although unintended suggestions inseparable from our present attitude toward the treatment of disease. The hysterical and highly suggestible neurotics usually suffer from the ailments and morbid states which are made fashionable in the community by the activities of successful physicians, surgeons, and specialists—have the complaints which they see around them and hear talked about. They constitute the great floating class of chronic invalids, who never die, who try one thing after another for the relief of one thing after another. They infest sanatoria, fill the waiting rooms of the specialists, bedevil the doctors, worry the surgeons, and are the bane of the neurologist's existence, but withal subserve a useful purpose, in that they constitute the reliable substratum of ailing humanity upon which many doctors depend for a living. They pass from one to another, try every treatment, operation, special procedure, patent medicine, and fake cure they hear of, and in the end are possessed of seven devils worse than the first. A classic example of this class, in a twenty years' search for relief from psychoneurotic disorders due to suggestion, had the muscles of the eyes clipped and glasses fitted, a stricture of the rectum dilated, a kidney anchored, the appendix and both ovaries removed, the uterus curetted, and a cervical tear sewed up, and a gastroenterostomy done; was treated in five sanatoria and went through the usual forms of hydrotherapy, electrotherapy, massage, mechanical vibration, and manipulation; had her stomach washed out and tried all the diets; took all the patent medicines her friends told her of, established several drug habits, wore a liver pad, went to the osteopaths, tried homeopathy and Christian Science, two divine healers, and several of the newest methods of medical psychotherapy. Why? The answer is, she suffered from a succession of symptoms, caused by the morbid suggestion, inseparable from medical, surgical, special, or any other treatment which disregards the vulnerability of this class of patients to suggestive influence. The moment we suggest to or agree with the hysterical patient that the condition complained of is such as to need treatment, that moment we create the disease which we subsequently cure, or pass along to the doctor with the newest therapeutic method. Do we not sometimes do harm rather than good? Do we not make as much psychoneurotic disease as we cure? Do our

methods of treating hysteroid perversions of function surpass or even equal those of the osteopaths, Christian Science experts, and divine healers? It is an open question. Measured by immediate results they, and even the plain fakirs, often beat us out of sight. Why? They make a more or less skilful use of psychotherapeutic suggestion, without, as we do, creating new nervous syndromes to replace the old. The failure of medical practice in the treatment of hysteria and hysteroid conditions is the reason for the existence of the modern religious cures and the quack "pathies." And frank recognition of the failure of our active and materialistic methods in relieving hysteroid and pithiatic disorders lies behind the present and growing interest in psychotherapy on the part of the leaders in medical thought. I make psychotherapy synonymous and coextensive with the treatment of disease by suggestion. Suggestion is not new. It is as old as the human race. It has been used for all time by all persons who wished to make some other person, sick or well, feel, think, or act differently from what he or she was previously doing. It is older by far than the reputable science of medicine. It was the only weapon of the prehistoric tribal medicine man. Fifty years ago it made the old doctors' medicine do more good than the young doctors' medicine did. Nowadays it makes the old doctors' patients go to the young doctor with the newest and most elaborate therapeutic equipment. It is used now, today, by all of us in the treatment of every patient and of every disease —sometimes consciously, more often unconsciously. It makes the Latin prescription do more good than the same medicine purchased at the drug store under its familiar name. It makes bread pills move the bowels, hypodermics of water relieve pain, sugar of milk sure epilepsy, and surgical operations relieve hysteria. In short, it is a valuable, even though at times unbidden, assistant to us all, and the mainstay of the fakir, who after all, from a psychotherapeutic point of view, may not be such a fakir as we say he is. From thus employing psychotherapy unknowingly and without conscious purpose; from even letting ourselves be deceived by a successful result into belief in the material efficacy of some meaningless modes of treatment, we have risen to a glimmering comprehension of the importance of the suggestive element, and are beginning to consciously use, to study, to outline and describe, to label and claim as our own this psychotherapeutic waste land.

Of the systems or modes of psychotherapy which have been elaborated, named, and more or less reputably employed by physicians in modern times, hypnotism or hypnotic suggestion is the simplest and probably the most familiar. While in a limited field, hypnotism has almost limitless power of temporarily modifying feeling, belief and consciousness, as well as of removing for the time being the subjective symptoms of disease, its sphere of application is narrow, and the psychic end-result almost uniformly unsatisfactory. It does real and serious injury to the mentality of the person subjected to it, and the employment of major hypnotism in medicine at the present time may be regarded as unjustifiable and a thing of the past. Many also regard it as unnecessary, obtaining equally good or better results by one or other of the numerous modifications of the procedure varying among themselves in the mode of production of the hypnosis, its degree, the character of the suggestions given, and in the "stage setting," but agreeing in that suggestion is used as such, impressively and confidently, with the patient in the waking state, or in a state of partial or minor hypnosis.

Occupying the place formerly held by hypnotic suggestion and its modifications we now have several newer and more complicated forms of psychotherapeutic procedure in which the fact that suggestion is employed is kept in the background and emphasis is laid upon other features of the treatment. Under this heading will properly fall much of our formal modes of medical treatment, in particular the rest cures, water cures, movement cures, diet cures, etc. The most comprehensive of them all, however, as well as the one which, properly used, gives the best results, is the reeducational psychotherapeutic method of Du Bois and his followers. In this, therapeutic use is made of careful history taking, and the tactful establishment of proper relations between patient and physician, the outgrowth of unhurried attention to and interest in the psychic as well as somatic detail of the case. After careful examination the nature of the disorder, the meaning of the symptoms, the cause of the morbid feelings, the probability of cure, with outline of the method to be employed in bringing it about, are explained to the patient at length, with all needed repetition, argument, persuasion and insistence. The attempted psychic impression is of the nature of reeducation, i.e., the patient is converted to the point of view of the physician and to his beliefs about disease, and is taught right thinking as well as right living. In connection with this conversational reeducation full use is made of isolation, rest, change of environment, improved nutrition, regulation of secretions, with correction of injurious habits, and of any essential pathological condition. The symptoms of associated but nonessential local or general disorders are disregarded and the patient is taught to ignore them. In other words, care is taken to prevent injury from the suggestion which would likely follow any exhibition of interest in local pathological suggestive symptoms. This plan of treatment has given good results and obtained considerable vogue. It is less of a narrow or arbitrary system of psychotherapy and more of a general attitude toward psychoneurotic disease. It treats disease as such from the point of view of the neurologist and internist rather than that of the psychologist. It attaches little importance to drugs, electricity, manipulations, surgery or other active interference with local symptoms, and great importance to rest, occupation, nutrition, environmental influences, right living, and sane thinking. It seeks the truth and tells no lies. In short, it includes more of the elements of medical common sense and honesty than are embraced in some of the other equally well-advertised methods, and is withal a procedure which any reputable physician with the needed training in neurology and internal medicine might feel free to use without sacrifice of his materialistic conceptions of the nature of disease, and without coming into competition with the religious cults and faith cures. In truth, with some limitations and with the personal modifications and variations required to adjust it to our special field of interest and therapeutic prejudice it is employed by most of us (although all of us do not know it) in the treatment of chronic dyscrasic and psychoneurotic ailments. The Du Bois method is in brief a Weir Mitchell rest cure in which massage, electricity, etc., are substituted by a form of

argumentative and persuasive reeducational suggestion.

Of the distinctively psychologic methods of mental healing, that popularized by Freud may be taken as the type. It is also the one which is at the present time attracting most attention. It is difficult to give any very intelligible account of it in a few words, or to avoid thereby doing some injustice to Freud, but with apologies to the reader and to Freud for attempting the impossible, I submit the following as a basis for preliminary orientation. Freud's conception of hysteria is somewhat at variance with that adopted in the preceding portions of this paper, in that emphasis is not placed upon the basis of degeneracy, and the influence of suggestion as such is, as far as possible, ignored. Instead, Freud recites the fact that the mental content of any individual at any period of his existence is the resultant sum of all impressions, feelings, emotions, thoughts, states of consciousness, etc., previously experienced; and that much of this mental pabulum is elaborated into our consciousness, our personality, and put into relation with and subjected to control by the mechanism of reason: consciously remembered, given its normal emotional value; normally reacted to, and used in conscious direction of feeling, thought, speech, and conduct. Certain mental experiences, however, which are unpleasant, painful, disappointing, mortifying, especially those experiences, thoughts, and actions for which we feel regret and shame, experiences which we earnestly wish had not occurred, we try to forget, to deny to ourselves, to repress, and to drive from conscious memory. We refuse to weave them into the mental fabric, refuse to acknowledge them as ours, we try to ignore them, and in some instances do force them from consciousness and seemingly "forget" them. In so doing, since by the law of conservation nothing is lost, the "forgotten" experience is forced into the subconscious where it constitutes a species of "psychic trauma," and persists as a foreign body. In the process of forgetting we heal the superficial, conscious wound, but leave its cause, the essential injury, unremoved. These painful experiences and their memories having never been accepted and normally reacted to by the conscious emotional and intellectual mechanism, have not become incorporated with the main stream of consciousness, nor brought into proper relation with the reasoning faculty. Therefore they are not subject to the control of the will. The condition is to be regarded as a pathological splitting of consciousness, in that the experiences thus relegated to the subconscious have undergone dissociation, being detached from the main stream of consciousness. They constitute wild and uncontrolled offshoots from the mental stem. At subsequent times, these suppressed ideas, having undergone growth, development, and transformation, reappear in consciousness in an altered form, powerfully affecting conscious thought, feeling, and conduct, but being entirely unrecognized as recrudescent painful ideas. They constitute, when they thus reappear, the symptoms of hysteria. In other words, the sensory disturbances, paralyses, tremors, spasms, convulsions, aphonias, amblyopias, and other somatic as well as all of the mental phenomena of hysteria are merely reappearances, transformations, conversions of former mental pains, which have been denied their conscious recognition and normal emotional expression, and have been thereby submerged and repressed for years in the realm of the subconscious.

The correction of this splitting of consciousness, the healing of the mental trauma, the cure of the hysterical symptom, is accomplished (and can only be fully and properly accomplished) by reuniting the dissociated experience with the main stream of consciousness. This can be done by tracing the hysterical symptom back to its original cause, by uncovering the forgotten shame, confronting the patient with it, compelling its recognition and acknowledgment, making the patient live over the experience in memory and in speech, and forcing him to undergo the painful emotional accompaniments thereto. In this way it is plucked from the subconscious, and thrust into conscious and normal relation with the remainder of the mental fabric, incorporated with the conscious mind, placed under the control of the reason and of the will, and given its proper emotional expression, and educational value. As soon as the dissociated experience is thus removed, the torn and twisted limb straightened and regrafted upon the main stem, the uncontrollable pathological equivalent, the hysterical symptom, disappears and the hysteria is cured.

Freud's method of treatment is based upon the foregoing. In its practical application it consists in having the patient, after being put at rest in a recumbent posture and given a brief preliminary explanation, recount his past history in utmost detail, it being insisted upon that he tell everything, and relate all of his thoughts exactly as they occur to him. When conscious recollection is exhausted recourse is had to skilful and tactful questioning, and to the use of test words after the method of Jung. He is also asked to relate his dreams, and these are subjected to careful psychologic analysis and brought into proper relation with the conscious idea associations. By the employment of these aids to conscious memory the patient is made to recall much that was seemingly forgotten—made to empty himself of his subconscious as well as conscious memories. In the course of time the one or more deeply buried painful experiences, almost invariably youthful sexual lapses or similar causes for regret and shame, are brought to memory, confessed by the patient, often with much mental distress and emotional outpouring. And then the hysterical symptoms disappear and the patient is well.

The theoretical considerations upon which Freud's method of treatment is based embody little that is not more or less familiar in psychologic thought, although the phraseology is novel and the point of view somewhat changed. In theory the method of psychoanalysis is attractive and makes a certain appeal to minds of psychologic bent, and its study is an intellectual exercise both inspiring and instructive. Freud himself is a psychologist of exceptional attainments by innate capacity as well as high training and long experience. Neither the theory nor the practice of the psychoanalytic method, however, are original with Freud, but were employed by Pierre Janet and others many years ago. Joseph Breuer, who was Freud's teacher and in association with whom much of Freud's early work was done, used the method quite extensively in practice. Breuer and Freud were using the treatment and publishing papers in collaboration when I was in Vienna in the early nineties. The procedure has been more or less familiar in Continental Europe for some years, but only during the past few years has it attracted attention in America.

Breuer, in allusion to the psychic emptying to which the patient is subjected, bluntly named it the "cathartic method." Freud speaks of it as the "psychoanalytic method." Some of the scoffers call it the method of "soul massage." Freud's earnestness and his signal success have attracted much attention, and made many disciples, who are, it is proper to note, among the most celebrated and highly trained members of the medical profession.

Freud recognizes the limitations of the treatment and advocates its use in selected cases only, and especially in the highly educated classes and for those cases not relieved by simpler means. He disregards the role of suggestion in his psychoanalysis, or even at times denies the influence of suggestion in the results obtained. Nevertheless, when broadly viewed and when divested of its nonessential dress it is found to be a method of highly specialized psychological suggestion, employing the ages' old and perfectly familiar methods of the Catholic confessional, the therapeutic value of which Breuer and others unconsciously stumbled upon by way of the careful clinical history insisted upon by the neurologist, the internist, and the Du Bois psychotherapist. The procedure is too highly psychological to be widely applicable, too time-consuming (Freud spent some hours a week for three years "analyzing" one case), necessitates an objectionably intimate and confidential relation between physician and patient, and withal is a complicated, cumbersome, and roundabout way of accomplishing what other methods, including those of the quacks and the pseudoscientific religionists, bring about by simpler and more direct means. The one reason for its existence is found in the fact that to the overdeveloped, overeducated sexual perverts and hysterics of the dilletante and professional classes the simpler forms of psychotherapy do not always appeal. Freud's psychoanalytic procedure offers them something in the way of psychic sexual stimulation and gratification of morbid egoism and in keeping with their intellectual development. Among the reported favorable results the preponderance seems to be among sexually starved old maid teachers. While some very distinguished members of the profession in this country have announced themselves as disciples of Freud and employ his methods in practice, it is my belief that while Freud and his group have made a notable contribution to morbid psychology, and to the science of psychotherapy, and have unquestionably effected numerous cures, the method of treatment will not gain many adherents among the medical men who use the English tongue.

Before leaving the subject of psychotherapy, I ask you to remember that the treatment of disease by suggestion is inseparably incorporated with many of the religious systems past and present, some of which had their origin in and derived their chief initial impetus from the power possessed by their earthly exponents to cure disease and even to raise the dead. Before the dawn of biological science, priests and physicians were one, and treated all sickness as well as sin in the same way, casting out the devils of disease and unbelief by some form of religious psychotherapy, that is by incantation, prayer, laying on of hands, or, in later times, by impressive ritualistic and musical procedures, by the powerful suggestive influence of the confessional, by pseudo-religio-scientific syllogism, etc. Upon even the most normal and stable intelligence the oft repeated injunction, "believe, have faith, confess your sins, make atonement, and your bodily ills as well as your sins will leave you," exert, when silhouetted against the unsolvable mystery of the unknown, a suggestive influence almost incalculable, and the innumerable cures of hysteroid disease brought about by such means, not only in ancient times, but in this later prosaic twentieth century day, are evidence of the curative powers of suggestion, as well as of the fact that in discussing psychotherapy we are not dealing with anything novel or progressive. The newest religious cures of our day, the newest and most "scientific" of the medical methods of suggestion therapy, are, all of them, atavistic and reversionary in tendency, merely representing survivals of or reversionary return to the undifferentiated religio-medical practice of the days when the world was young. All systems of psychotherapy depend for success upon two factors, mystery and novelty. As soon as the mystery is solved, or the novelty worn off, the skeleton of suggestion which gave them what real power they possessed, is found no longer useful until it is dressed in new clothes and given a new, high-sounding and misleading name. For this reason all methods of treatment depending in any degree upon suggestion have given best results in the hands of their originators and their early converts. Time, investigation, wider knowledge, and unprejudiced criticism usually prove fatal to them.

Study and discussion of psychotherapeutic methods are in the plain line of duty of those who wish to contribute to medical progress. The erection of the facts of suggestibility into systems and methods of practice, and their indiscriminate use in the treatment of disease, to the exclusion of other and preferable measures of known and proven value, verge close upon quackery, to say the least. Our scientific attitude toward disease should be that of the biologist; our professional attitude, that of the physician, hygienist, and sanitarian, dealing with disease as a material process. And let the sick souls seek, if they must, their priestly comforters. Let the religious healing cults and quack pathies coin ignorance and atavistic suggestibility into dollars. But let us refuse to compete with them. Since at the present stage of our social development doctors are probably a necessary evil, and since we must even take money for curing disease, and for trying to cure it, our seemingly necessary and unavoidable psychotherapy should be employed with judgment and with restraint. However employed it should be based upon the largest measure of scientific medical knowledge obtainable and be used at least with honesty. Better than any "system" is that valuable psychotherapeutic influence which takes the form of and is synonymous with confidence in the doctor—confidence on the part of the patient, based upon the belief that the doctor knows, and is doing what is best, confidence in himself on the part of the doctor, based upon the fact that he knows that he knows what is best, and is doing it. The spirit of scientific truth should withal make us unwilling to create local hysteroid symptoms by even unconscious suggestion, should make us slow to adopt medical fads, skeptical toward the newest up-to-date therapeutic discoveries, should make us cautious in attributing the cure to the treatment, should make us more than suspect that the relief comes from the hidden, unconsciously employed suggestion.

In conclusion, let us remember that pathological credulity and suggestibility with their hysterical

and other psychoneurotic derivations are symptoms of reversionary weakness—are in themselves *prima facie* evidence of degeneracy. Some day in the fulness of time a race of men will be born with the courage to deny to the degenerate the privilege of reproducing his kind, of handing down his heritage of weakness and sorrow to succeeding generations. In that day hysteria and its psychotherapeutic cures will join witchcraft and voodooism in the museum of medical antiquities, and the religious and medical psychological suggestion mind healers will be free to employ their talents in less atavistic lines of endeavor. And then we will be able to treat hysterical and pithiatic phenomena in the right way—not by suggestion of any kind, whether used under its own or masquerading under another name, not by fakes and frauds, but by educational and eugenic measures, curing the specific symptom in the individual by simply letting it alone. Just as soon as the hysterical symptom attracts no attention, elicits no sympathy, causes no agitation, distress, nor other suggestive emotional state on the part of the onlooker, it dies for want of nourishment, and a real, basic, and indisputably lasting cure is obtained. Caused and nourished by suggestion, it perishes for the lack of it. This method of treatment will be generally employed when the millennium arrives. In the meantime, as Dr. Walton says: "Why worry? Even today an ounce of Muldoon is worth a pound of Freud."

166 Conti Street.

EXPERIENCES WITH DUODENAL ALIMENTATION.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

In two previous papers†‡ I have shown that we are able to keep the weight of the body in equilibrium for a longer period by duodenal alimentation than by any other method. Together with Dr. Rosenbloom** I stated that during duodenal alimentation there need be no nitrogen loss. In the following communication I shall record my experience with this method of treatment, which extends over a period of two years and covers in all thirty-four cases (six of which have been previously described). I shall first describe a few of the newer cases as typical examples and then tabulate all of the twenty-eight new ones.

Case I.—February 15, 1911. A. S., 37 years old, has always been well with the exception of an attack of malaria twenty-one years ago. About nine years ago his present trouble began, consisting principally of pains one hour after meals. In 1903 he was operated upon for appendicitis. As this procedure did not seem to benefit his condition, he was again operated upon in 1907 for adhesions and later, in 1909, for ulcer of the stomach. At the last operation no ulcer was found. The patient indulged moderately in alcohol and tobacco and never had syphilis. Six weeks ago he began to complain of pains in the epigastrium which radiated to the right iliac fossa. Around the umbilicus the pains are cramp-like; in the right iliac fossa they are sharp and cutting. The pain becomes more bearable when the stomach is full; one hour after meals, however, it begins again and is then associated with acid eructation, burning, and waterbrash. There has never been any vomiting or jaundice. His appetite is good, his bowels are regular, and he feels comparatively well.

Present Condition: Patient is a well-developed and well-nourished man. Heart and lungs are normal. The abdomen shows two operation scars (one in the region of the appendix, the other over the gall-bladder). Between the navel and the pubic bone there is a point of tenderness. The pressure over this point causes pain in the epigastrium. The region of the gall-bladder is also sensitive to pressure. The urine is negative, the temperature is normal, and the pulse 68-72. Examination of the stomach contents showed HCl = 64; acidity = 86. No food remnants from the day previous. Examination of the stool for blood by means of the guaiacum test was negative. The benzidin test, however, owing to the presence of imperfectly digested meat fibers, gave a positive reaction. The patient was put upon calcined magnesia and bismuth. On February 22 the thread test was used. The duodenal bucket went in to 77 centimeters. The lower 17 centimeters were stained with bile and a blood spot five centimeters in length began at 47 centimeters from the teeth. On February 27 patient was placed upon duodenal alimentation. He felt better at once. He had no sour eructation and no distress after the feedings. He was nourished every two hours, receiving eight ounces of milk, one raw egg, and a tablespoonful of lactose eight times daily. During the entire time the bowels were normal. On March 9 the duodenal tube was removed. On March 10 the thread test gave a negative result, *i.e.* absence of blood spots on the thread. The patient has since then (March, 1911) felt perfectly well without any of his former distress.

Case II.—May 15, 1910. Sister R. M. has been sick for four years. Her last attack occurred in January. She complains principally of vomiting after meals; pains in the left side of the abdomen, particularly after partaking of food; nausea; eructations, especially at night and since her operation (uterus) more frequent than before. She is constipated and during the last two years has had bright blood in the stool on three or four different occasions. Generally the bowels are constipated. On January 15 she vomited half a glassful of bright red blood and smaller amounts in February and March. During the past two years she has lost from twenty-five to thirty pounds. The patient has pains after having partaken of food (even with a strictly liquid diet), and vomits two to three times daily. Examination reveals considerable tenderness to pressure in the epigastrium and a somewhat dilated stomach. The thread test gives a negative result in reference to discoloration by blood, but shows, however, that the pylorus is permeable. The patient was placed upon duodenal alimentation. Immediately after commencing this method of treatment there were no pains in the stomach. After two weeks' treatment the duodenal tube was removed and the patient placed upon a diet of milk and eggs. Later on gruels were added. The patient felt well, gained in weight, and recovered entirely.

*Read before the New York Academy of Medicine February 15, 1912.

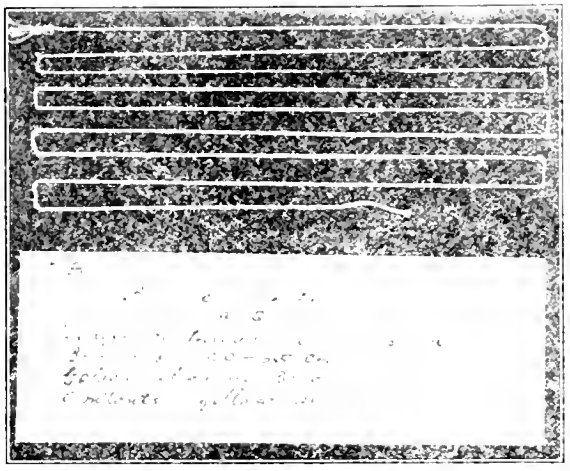
Case III.—December 20, 1910. Adalberto S., physician, 38 years old, had eight years ago a right-sided pleuropneumonia. Family history was negative. He does not drink, smokes a great deal, however, and for the past twenty years has been taking daily two cups of strong coffee. Although he has

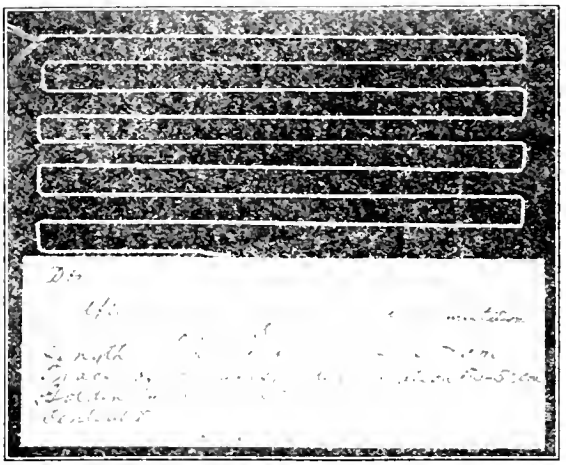


at times eaten too fast he always masticates well. Fifteen years ago he began to suffer from pains in the abdomen, occurring at first at longer intervals, later every three or four months, and for the past two years on an average once or twice a month. Nervous excitement and irregular meals make him worse. His attacks vary in intensity. In the light attacks his tongue is coated, he feels a burning and dull pain in the stomach which disappears again after a meal. The appetite is normal. In the attacks of medium intensity he has besides the symptoms just described a diminished appetite, a feeling of fullness and pressure in the epigastrium three or four hours after meals, rarely in the morning, and sometimes in the evening. Vomiting or eructations are not present. There is, however, some nausea which disappears after the taking of alkalies, especially if they cause belching. The most severe attacks, of which there have been five or six in the past two years, are accompanied by loss of appetite, nausea, and vomiting, sometimes immediately after meals, sometimes three or four hours later. The vomited matter is not distinctly acid, contains mucus, and is of a white color, sometimes reddish, however, or of a chocolate color. The attacks are not alleviated by alkalies in any manner, but only by vomiting or a recumbent position. These attacks are also frequently associated with headaches, lassitude, and somnolence. Sometimes the patient suffers from vertigo, nervousness, and a bad taste in the mouth. Occasionally slight palpitation of the heart and dyspnea occur. The movements of the bowels are punctual and regular at the same hour. There is never any blood or mucus in the stool. During the past two years he has lost five pounds. His memory is not as good and he cannot concentrate his mind as well as formerly.

Examination reveals a dilated stomach, reaching to about three fingers' width below the umbilicus. December 16, 1910, examination of the stomach contents one hour after a test meal showed HCl +; free HCl, 80; total acidity, 100. The thread test on December 17, 1910, showed a brown discoloration between 50 and 55 centimeters, and golden yellow between 60 and 80 centimeters, pointing, therefore, to an ulcer of the stomach, with permeability of the pylorus. On December 17, 1910, duodenal alimentation was begun and continued for twelve days. On January 4, 1911, after the period of duodenal alimentation the thread test showed only traces of a brown discoloration. The photographs of the thread test of Dr. A. S., both before and after duodenal alimentation, illustrate this very well (Figs. 1-2). The case of Dr. A. S. is interesting for the reason that clinically it appeared to be one of duodenal ulcer. The thread test, however, showed that the ulcer was situated in the stomach and not in the duodenum.

Case IV.—Miss Lily D., 26 years old, has always been well with the exception that she had measles, typhoid fever, and grippe. For the past four months she has been suffering from pains in the epigastrium and an acid taste in the mouth occurring generally fifteen minutes after meals. She belches a great deal but never vomits. She is constipated and has lost ten pounds in four months. The appetite is fairly good except during the last few weeks. At times she feels weak and occasionally faints, especially at church. She, however, always recovers and says that a short time ago she vomited a quart of blood. Examination of the stomach contents on February 6 reveals: HCl = 0, total acidity = 10, no occult blood. Duodenal alimentation was instituted from February 3 to 14, 1911. A thread test made on February 16 showed no blood spots.

Gastric and duodenal ulcers form the main contingent for this method of treatment, although other conditions, such as nervous vomiting and atonic dilatation of the stomach can also be favorably influenced thereby. Two years ago I made the observation that some ulcers of the stomach or duodenum are not entirely cured after two weeks of duodenal feeding, although the patient feels perfectly well or better than before. This can well be demonstrated by the thread test. In a number of cases of ulcer in which the thread test was positive, I have tried to exert a local influence upon the ulcerated surface, by coating the duodenal tube at the corresponding place with a solution of protargol. The latter is prepared as follows: protargol, 5 grams; agar, 5 grams; gelatin, 18 grams; glycerine, 25 grams; distilled water, up to 100 cubic centimeters. The solution is heated in a water bath until it assumes the consistency of a syrup and then the place on the



duodenal pump corresponding to the seat of the ulcer is dipped into this solution. It is then allowed to cool and solidify in the air and is then placed for half a minute in a 5 per cent. watery solution of formalin, after which it is dried. In coating the tube with the protargol solution we calculate back-

TABLE OF NEW CASES OF DUODENAL ALIMENTATION.

No.	Name	Diagnosis	Length of duodenal feeding	With or without coating of protargol	Thread Test		Remarks
					Before duodenal feeding	After duodenal feeding	
1	Henry T.	Ulcer near pylorus	14 days	With	Blood at 56 cm.	No blood	
2	Miss H.	Gastric ulcer	14 "	Without	Blood at 42–46 cm.	Blood trace at 46 cm.	
3	Dr. A. S.	Gastric ulcer	14 "	With	Blood at 50–55cm.	Blood trace at 50 and 52 cm	
4	Mrs. D. S. M.	Gastric ulcer and cholecystitis	14 "	With	Blood at 44–50 cm.	No blood	
5	Mr. A. B. R.	Gastric ulcer	14 "	With	Blood at 47–52 cm.	Blood at 48–52 cm.	
6	Miss J. E. C.	Duodenal ulcer	13 "	Without	Blood at 59–61 cm.	No blood	
7	Mr. O. S.	Duodenal ulcer	11 "	With	Blood from 54–58 cm.	Minute bloodspot at 61 cm.	Stomach reached to the pubes before treatment; afterwards only to navel.
8	Mr. W. P. D.	Gastric ulcer	14 "	With	Blood from 52–68 cm.	Blood from 51–65 cm.	
9	Mrs. H.	Gastric ulcer	14 "	Without	Blood from 30–45 cm.		Pylorus palpable and painful on pressure.

ward from mark 80 on the tube, as for instance if the ulcer is 44-46 centimeters from the lips, we coat the tube 44-46 centimeters from mark 80, because the latter mark is the one which lies between the lips during the treatment. It is better to make the coating a little more extensive, so that if there are slight differences in position of the tube the protargol will still act.

In order to judge more accurately the result of protargol treatment we have treated some of the cases with and some without the protargol coating. Of course we can take only those cases for comparison in which the thread test has been made before and after duodenal feeding. Of the fourteen cases undergoing protargol treatment, in whom the thread test was at first positive, it was entirely negative in five cases after duodenal feeding; in three there was only a trace of a blood-stain, whereas in six the test remained positive. In seven patients without protargol coating the thread test after duodenal alimentation was negative in four, positive once, and twice showed traces of blood. It would seem from these statistics that the coating of protargol is of no value. The number of cases, however, is too small to enable one to draw definite conclusions from them and it will be necessary to test the method in a larger number of cases.

The duodenal feeding apparatus as well as the method of its insertion I have already minutely described in my previous papers. Here I would like to state, however, that while ordinarily the duodenal pump reaches the duodenum within two to six hours, this takes much longer under certain conditions, principally when a high degree of pylorospasm is present. In several of the patients we had to wait fully twenty-four hours, in one even thirty-six hours, before the end of the tube entered the duodenum. Inasmuch, however, as the patients during the migration period of the tube from the stomach into the duodenum, partake of liquid foods by the mouth, there is not much loss by waiting.

As a nutritive medium I have used a mixture formerly suggested by me, consisting of milk, egg, and lactose (200 to 240 c.c. of milk, one egg, and 15 to 30 grams of lactose every two hours). At times we have added cream in order to increase the nutritive value: sometimes we omitted the milk sugar when there was a tendency to loose bowels. In one case, Miss E. S., we had to discard the milk entirely, since she had a marked idiosyncrasy for this substance, even when passed directly into the duodenum. Severe abdominal pains resulted as well as diarrhea. In this case we used the following scheme of nutrition: 7:30 A.M., oatmeal gruel, 180 c.c., one egg, butter, 15 c.c., lactose, 15 c.c.; 9.30 A.M., pea soup, 180 c.c., one egg, butter, 15 c.c., lactose, 15 c.c.; 11.30 A.M., the same as at 9.30 A.M.; 1.30 P.M., bouillon, 180 c.c., and one egg; 3.30 P.M., oatmeal gruel, 180 c.c., butter, 15 c.c., one egg, lactose, 15 c.c.; 5.30 P.M., pea soup, 180 c.c., butter, 15 c.c., one egg, lactose, 15 c.c.; 7.30 P.M., the same as at 5.30 P.M.; 9.30 P.M., bouillon, 180 c.c., and one egg. Total daily quantity oatmeal gruel, 360 c.c.; pea soup, 720 c.c.; eggs, 8; lactose, 90 c.c.; bouillon, 360 c.c.; butter, 90 c.c. The pea soup was made from Knorr's pea flour, one tablespoonful to 250 c.c. of water which was boiled down for from one and a half to two hours to 180 c.c.

It is self-evident that many more substances might be utilized for duodenal alimentation. The main point to be observed is that the mixture must be a very fine fluid emulsion, without any coarser particles, so as not to clog the narrow duodenal tube. It is therefore best to filter the mixture first through a fine sieve or through gauze. If these rules are observed there will rarely be any difficulty. As I have mentioned before the duodenum itself is not very sensitive; the patient does not feel when food or air is introduced into it. The duodenum is, however, sensitive to heat, cold, and distention, when the normal conditions are absent and various general symptoms result as a feeling of weakness, restless-

ness, cold perspiration, sensation of heat, or distention in the stomach, etc.

Sensations experienced during the period of duodenal alimentation: I have requested several patients to write up their sensations during the period of duodenal alimentation and reproduce a few of these descriptions as follows:

Dr. A. S.: "The swallowing of the tube is not difficult and not painful. It does not cause nausea in the stomach as one would be likely to think. The presence of the tube in the throat and mouth is somewhat disagreeable, but causes, however, no difficulty. Only during the first few days a little nausea was produced by contact with the uvula. Since sufficient food was taken (eight ounces of milk and a raw egg every two hours) no appetite was experienced during the first nine days. Later on appetite set in occasionally in the morning, but never in the day. Feeding through the tube is easy; the duodenum, however, is sensitive to excesses of temperature, either cold or warm, as well as to the amount of pressure used in introducing the food. A medium temperature and slow introduction are best, otherwise a feeling of fullness occurs, accompanied by belching." Another patient says: "The only disagreeable part of duodenal alimentation is during the initial swallowing of the tube and for the first few hours thereafter, until one has become accustomed to its presence. In the stomach itself there is no sensation whatever, either agreeable or disagreeable, after feeding. One can feel the warm temperature of the food as it passes by the lips through the tube, and a slight distention of the bowel, but neither pain nor hunger. In the morning the appetite is keener, but is, however, completely satisfied by the introduction of food through the tube." Miss F. says: "At first the sensation was pretty nearly unbearable. After the first feeding a feeling of nausea and profuse perspiration occurred. It seemed as though the food wanted to regurgitate, and frequent eructations were present. Later there was a sensation of burning in the stomach. It felt as though the food entered the stomach." Mr. L. has no sensation except a feeling of fullness and warmth at the end of feeding.

The results of duodenal feeding are very satisfactory. We must, however, add the following explanation: Subjectively all but one case (Case 10, George S., tuberculous ulcer of the stomach) were distinctly improved. That means there were present either no pains at all or only very slight pains after the partaking of food. Nearly all the patients were able to eat an ordinary mixed diet a few days after the period of duodenal alimentation. A marked increase in weight was later on observed in most of the patients. Objective improvement I was able to find in three ways. (1) In some cases, in which the pylorus could be felt as a small oval swelling (about the size of a walnut), probably caused by a spastic condition, the tumor disappeared during the period of duodenal feeding and did not return afterwards. (2) In nearly half of all the cases of ulcerations of the stomach and duodenum, in which before duodenal feeding the thread test was positive, it became negative after treatment. This would point most likely to the fact that an actual cure of the ulcer had taken place. (3) In some marked cases of ptosis and dilatation of the stomach a considerable change of the position and size of the stomach during the period of duodenal alimentation was observed. In R. S. (Case 14), O. S. (Case 7), and Mrs. McQ. (Case 17), the organ became much smaller. In all these three cases the stomach before treatment extended down to the os pubis, as could be easily demonstrated by the splashing sound; after treatment, however, the lowest part of the organ was found one finger's breadth above the navel in Mrs. McQ., and in the region of the navel in R. S. and O. S. This was found in the course of the examination, and may be of great therapeutic value.

We might try to study the influence of duodenal nutrition in atonic dilatation of the stomach. According to my observations this method of treatment ought to be successful in such cases. Taken all in all, we may assert that duodenal alimentation is a therapeutic measure of considerable value in suitable cases, and can be warmly recommended.

PRELIMINARY NOTE ON SOME EXPERIMENTS ON SEROUS SAC DISTENTION.

By A. A. SMITH, M.D.,

NEW YORK.

THE title of my paper as given on the card is misleading. I have been making some studies of the anatomy and pathology of the pericardium and pleura, especially in relation to the filling of them with fluid and the effect of such filling on the question of distensibility of serous sacs, and in respect to the pericardium and its influence on the displacement of the heart. I hoped that in connection with these studies and the use of the *x*-rays I might be able to determine the effects of displacements of the heart in pericarditis with effusion. These studies are by no means conclusive, and I might also state that they are not concluded.

First, in connection with the pericardial sac. For a long time it was thought that fluid in the pericardial sac when in considerable quantity would frequently displace the apex to the left and upward. The observations that were made placed the apex in the fourth intercostal space, and on the nipple line or to the left of it, some observers even making it higher up. These observations were based on the fact that a very decided impulse in many cases was found in the fourth intercostal space, and that the maximum intensity of the first sound of the heart was found in the same situation as the impulse, these two signs being relied on to locate the apex.

There has been a great diversity of opinion among observers as to whether this ever occurs. Dr. William Ewart contends that the apex is not lifted, but that the impulse felt in the third or fourth space is the base of the heart and not the apex. Dr. Roberts seems inclined to agree in part with this view. Balfour says the apex is pushed inward and removed from the anterior wall. Many observers contend that the apex has been noted lower than the normal situation. In such cases, however, the enlargement of the heart with a large quantity of fluid has pressed the diaphragm down, and as Dr. Ewart explains it, the heart assumes a more vertical position and is displaced more to the median line, the aortic arch becoming somewhat straightened.

Sansom makes the statement that the apex is above the normal, probably in the fourth intercostal

*Read at a meeting of the Practitioners' Society of New York, November 3, 1911.

space and to the left. To quote his own words, "the apex is tilted or floated upward." I consider the use of the term "floated," unfortunate because if the displacement is upward and to the left it could not be "floated." It makes no difference how dense the fluid is, the heart is of greater density and certainly could not be "floated." Thayer, in the Johns Hopkins Bulletin, 1904, says the position of the heart is still in dispute. "It is probably true, as Rendue and Ferrand state, that the heart remains in its normal postion while the diaphragm descends. Scott and Le Conte, in the *American Journal of the Medical Sciences*, say that it is not proven, as generally stated, that the heart is pushed away from the chest wall with a disappearance of the apex beat. The heart is fixed at the base and this leaves the apex free as a movable portion to be affected by pressure from all sides or any side. If adhesions exist between the pericardium and the heart on either the right or left side, a lateral dislocation of the heart will occur, or pressure by the filled pericardium as a whole may cause a lateral dislocation. Perhaps other unknown conditions within the pericardium will produce the same lateral displacement. It is probable that in some cases the pressure of fluid in the pericardium dislocates the heart to the right or to the left side."

Herschfelder quotes Pirogoff as saying that the heart sinks in the pericardial fluid and may lie against the vertebral column and away from the chest wall. Schaposchnikoff says the tendency of the heart is to remain near the anterior chest wall. This position is assumed even in the cadaver upon injection of the pericardial sac. The heart is held in this position, in spite of gravity, by the elasticity of the great vessels. When the vessels lose their elasticity the heart sinks to the bottom of the fluid. The apex is pushed up probably. Skoda and his followers taught that the displacement of the heart in pericarditis with effusion is downward and backward; Sibson, "the apex is displaced upward and outward by the fluid."

I have quoted all of these and could have quoted many more, to show the great diversity of opinion as to the displacement of the heart under conditions of effusion. Many factors must be taken into consideration. The elasticity or non-elasticity of the pericardial wall, the condition of the large blood vessels, the size of the heart, the quantity of blood in the heart at the time of the occurrence of the effusion, must all be taken into consideration.

A very important factor is the very great differences in the relative positions of the heart during life, with all its activities in the revolutions through which the heart passes constantly, and conditions and relative position after death.

Anatomically, the pericardium at the base of the heart has been shown to be more elastic, and consequently more distensible under normal conditions than the pericardium elsewhere.

While discussing this question at one time, a suggestion was made by Professor Edward K. Dunham which might offer an explanation of the manner in which displacement might occur. It is well known that the pericardium passes up over the base of the large vessels to a variable extent, some times as much as two inches, and this portion of the pericardium being more elastic and more distensible the accumulation of fluid distending this portion of the sac would act as a lever, and in this way do away with the objection offered by so many observers that the heart cannot be pushed up or "floated" from mere accumulation of the fluid below it.

Again, anatomically, the pericardium narrows very decidedly toward the base, and this fact, together with the greater distensibility of the pericardium at this portion of it, would add plausibility to the lever theory.

In a majority of cases the normal situation of the heart is oblique, from right to left and from above downward. This general direction readily lends itself to the explanation suggested by Prof. Dunham. It is assumed, of course, that the accumulation of the fluid must be very considerable in order to distend the sac, and that such distension occurs gradually. The probabilities are that the displacement of the heart is very variable and depends upon a great many conditions. The cases in which, as I believe, the heart is displaced upward and to the left, are those cases in which the heart anatomically is in its usual oblique position. The *x*-rays have shown that many hearts are situated normally more nearly vertical and some almost vertical, as is the case in quadrupeds; that in some instances there is a position of the heart which is much more nearly horizontal than the usual oblique position.

The distension of the pericardium at the base and over the large vessels acts as a lever to lift the heart when in this position and in this way displaces it upward and to the left. Undoubtedly inflammatory adhesions due to pathological conditions may influence the question of displacement. Again anatomically there are fibrous attachments which are normal and will probably hold the heart in such a way as to govern the question of displacement, these attachments varying in individuals.

The contention that the heart is held in position anatomically in such a way as always to prevent it from being easily displaced can hardly hold true, because the heart is very easily displaced from its normal position. As an example, the fluid effusion in the left pleural cavity, as is well known, will displace the heart very easily from its normal position to the median line, and in some instances with large effusions, even far beyond the median line to the right, showing the ease with which the heart may be displaced. Again, that tumors of large size in the abdominal cavity can displace the heart upward and to the left would seem to indicate that the heart may be easily displaced. Even tympanitic distension may do this.

I am inclined to take the position that clinically, at all events, the heart is displaced in some instances upward and to the left. Autopsies have shown that the apex may be to the left in the fourth intercostal space and held in such a position by more or fewer adhesions.

Let me give a case in part from the clinical standpoint. A patient was admitted to Bellevue Hospital a few years ago who had at the time evidences of fluid in the pericardial sac. This was readily made out. The patient's heart was apparently displaced so that the apex was in the fourth intercostal space and to the left of the nipple. This patient was kept under observation for a long time. The effusion in the pericardium gradually disappeared, but with the disappearance of the fluid pericardial friction sounds were very distinctly heard, and the apex still remained in the fourth intercostal space. My explanation at that time was that the patient had a pericarditis with effusion,

the displacement had occurred upward and to the left, the apex was in the fourth intercostal space, and that with this displacement adhesions had occurred and these adhesions were firm enough to hold the heart in its new position. This patient came to the hospital two years later and his heart apex was still in the fourth intercostal space. I merely give this as a type of a number of cases I have seen.

Experiments on the cadaver in this relation offer many difficulties; I am fully aware of that. The tissues are all in practically a fixed condition, the pericardial sac is practically wanting in elasticity, the adjacent lung structures are in a condition of quiescence, the heart itself is in a condition of quiescence so different from what it is in the processes of life, the large vessels likewise are in a condition of fixation with loss of elasticity. Even in the cadaver difficulties are experienced in the manner of introducing fluid into the pericardial sac for fear of changing the dynamics.

Professor Senior of the anatomical department of the University and Bellevue Hospital Medical College suggested a method of distending the pericardial sac, which, although it had difficulties of its own, did away with some of the objections to the experiments on the score of disturbing the relation of the pericardial sac with the surrounding structures, by opening the sac externally. The sac was distended by passing a cannula into the external jugular, passing it on down into the innominate in the superior vena cava, and then by way of the right auricle, and puncturing the heart wall without disturbing the relation of the structures. This was the method pursued in the examples which I shall give of distending the pericardial sac.

Experiment I.—Subject. Tubes with fluids of various specific gravity. No. 1 contained water, sp. gr. 1000; No. 2, bichloride of mercury solution, sp. gr. 1020; No. 3, lead acetate solution, sp. gr. 1020; No. 4, lead acetate solution, sp. gr. 1060. The shadows on the *x*-ray plate were dense in proportion to the specific gravity of the fluids in the tubes.

Experiment II.—Subject, male; Name, Bruno, age thirty-four.

Physical Diagnosis.—Subject had acute lobar pneumonia, involving the whole of the right lung.

Technique.—Injected 750 c.c. of lead acetate solution of a sp. gr. 1020.

Result.—Heart moved upward; pericardium uniformally distended.

Experiment III.—Subject, Martens Rheinhardt, age sixty-four.

Physical Diagnosis.—Subject had chronic tuberculosis.

Technique.—Injected 2000 c.c. of lead acetate solution, sp. gr. 1020.

Result.—Fluid passed through the pericardium into the right pleural cavity. The position of the body was suspended.

Experiment IV.—Subject, Pohern, Joseph; age sixty.

Technique.—Injected 1000 c.c. of lead acetate solution, sp. gr. 1020.

Result.—Injection entered the pericardium but returned into the right ventricle, the right auricle filling up and also pulmonary arteries as well as the superior and inferior venæ cavæ. This has been confirmed by autopsy.

Experiment V.—Subject, dog; weight twenty pounds.

Technique.—Dog given ½ grain of morphine sulphate. Anesthesia by ether. The dog was kept under constant artificial respiration. Pericardium injected with physiological saline solution, sp. gr. 1005.

Result.—The fluid entering the pericardium modified the cardiac activity, as shown by the following: As the fluid was injected the blood pressure dropped till finally the heart ceased to beat; upon the removal of the solution the blood pressure returned to its original height and the heart began to beat.

Experiment VI.—Subject, dog; weight thirty pounds.

Technique.—The same as in Experiment V, with a 2.4 per cent. solution of sodium chloride, sp. gr. 1015.

Result.—The same as in Experiment V.

18 West Fifty-first Street.

THE PLIGHT OF THE CONSUMPTIVE WAGE EARNER.

By JOHN F. RUSSELL, M.D.,

NEW YORK.

Associations, societies, and influential bodies of all kinds devoted to the study and betterment of the tuberculosis situation are working in perfect accord and using all their great influence in teaching and urging the practice of certain principles in the prevention and cure of tuberculosis. Harmony is desirable certainly, but it is of greater concern in an undertaking of such magnitude and so far-reaching in its effects that the principles taught and practiced, which influence, either directly or remotely, nearly every individual in the community, be correct. In certain important particulars I believe these principles to be wrong, and that their practical application results in the gravest injury to the largest and by far the most important body of tuberculous sufferers.

In order to make my meaning clear it is necessary first to review the present teaching and practice, and for this purpose they may be arranged under three heads, viz.: 1. Tuberculosis is a preventable and curable disease. 2. In the majority of cases tuberculosis is not a fatal disease. 3. The cardinal factors in curative treatment are rest, pure air, an outdoor life and nourishing food.

Prevention. The cause of the disease is known to be a bacillus, and because if all tubercle bacilli in the world were destroyed there would be no more tuberculosis every effort is being made to destroy all bacilli. The prevention of disease is the highest attainment of medicine, so, as between prevention and cure, the greatest energy is devoted to prevention—in educating and hedging about the diseased, who alone may disseminate bacilli, and in thus safeguarding the healthy against infection. The cure of the disease is secondary.

Cure. The statement that in the majority of cases tuberculosis is not a fatal disease cannot be based upon results of treatment, because the reports of cures from institutions devoted to the treatment of the disease are far less than a majority of patients treated. It must therefore rest upon reports of examinations made of bodies dead of other diseases in which cured tuberculous lesions were found. The percentage of cured lesions thus found varies with different writers, but in the main the results

of such examinations show that in a majority of cases tuberculosis is cured spontaneously. This will be alluded to again.

Present Aims. "By procuring the establishment, on an adequate scale, of hospitals for advanced cases of consumption, sanatoria for the cure of curable cases and dispensaries for early diagnosis and as centers of visiting, nursing and instruction in the homes of the poor." The latest announcement which I have seen says that there have been established over "15,000 beds for curable cases in 400 sanatoria for the open air treatment, the opening of nearly 300 dispensaries with more than 500 physicians in attendance, and with over 500 visiting nurses giving instruction in the homes of the patients." The foregoing quotations are taken from a publication of the National Association for The Study and Prevention of Tuberculosis, and it is perfectly clear from the language that no hope of cure is entertained from any method of treatment other than that provided at sanatoria. Dispensaries are not intended for the treatment of curable cases, but are employed to discover such, and, when found, send them to sanatoria, if possible, and as a means of instruction and palliative treatment. In the view of those who believe that pure air (distinguished from fresh air, the best that can be had in cities, which may contain dust and other foreign matter) and an outdoor life are essential for success, dispensary treatment can offer no prospect of cure. No systematic curative treatment is therefore practiced at these dispensaries. The hours of attendance are, broadly speaking, some time between 10 o'clock in the morning and 5 o'clock in the afternoon, Sundays and holidays excepted. The Tuberculosis Directory of The National Association for the Study and Prevention of Tuberculosis shows that for the whole United States there is but one dispensary which is open in the evening every week day, one which is open four evenings a week, four open three evenings, six open two evenings, and twenty-nine one evening.

By far the greatest number of the inhabitants of this country are occupied in some form of labor and are variously classified as wage earners, breadwinners, or, more comprehensively, as those engaged in gainful occupations. Every one who has given the subject consideration must know that in all large shops, offices, factories, everywhere, in fact, where numerous people work, there are many consumptives, the great majority of whom are curable. A large number cannot stop work even for a short time without serious sacrifice, and a still larger number cannot stop work at all lest they or their families or those dependent upon them suffer want. They cannot go to sanatoria if invited, they perhaps cannot afford to consult a private physician, or, if they do, are advised to stop work and go away; they cannot go to dispensaries because the hours of attendance at these institutions conflict with work hours or, if they do go they receive no curative treatment. If the disease is in the early stage there is so little discomfort, comparatively speaking, that the sufferers may drift on unconscious of danger, or, if they have learned that they have tuberculosis they have also learned that they cannot follow the advice offered. Their only alternative in this event is to seek the advice of quacks or use patent medicines. They find it an advantage to conceal the knowledge of their disease. If the disease advances they sooner or later reach the point where they either give up or lose their work and become dependent. They have ceased to be self-supporting; their disease is advanced; they have missed the chance of recovery. In many instances they have now reached the place where, for the first time, present methods may begin the work of prevention and cure. Of all deaths of males from tuberculosis in 1908 77.3 per cent. were deaths of males gainfully employed, whereas in the case of deaths of males from all causes only 52.3 per cent. were of those so employed.

It is bad to have tuberculosis, but to be denied curative treatment is indescribably worse. The bad is bad enough, for good health is the capital of these people, but the worst is without justification, because it is impolitic, immoral, and unnecessary.

For about fourteen years (March, 1898) I have been treating ambulant cases of uncomplicated pulmonary tuberculosis in wage earners at a dispensary without interruption to their labor. My purpose has been to work out by experience a systematic treatment which would yield the best results, and from time to time, as progress has been made, details of treatment and results have been published. The percentage of apparent cures reported and obtained in this way now exceeds the percentage of apparent cures reported from sanatoria. The following brief statement of the theory of the treatment employed at the Thompson Street Dispensary seems necessary for a clear understanding of this paper.

No one of intelligence can doubt that the immediate cause of tuberculosis is the growth and multiplication of tubercle bacilli, and on first thought nothing could seem more reasonable in preventing the disease than the effort to destroy all tubercle bacilli. In the light of recorded facts this reasoning does not lead far enough. In the first place, so many observations from trustworthy sources have been published showing the widespread occurrence of active and healed tuberculous lesions in dead bodies that even conservative writers are led to remark that if systematic inspection is made tuberculous lesions are found practically in 100 per cent. of the bodies of adults (Osler). This fact alone raises a doubt as to the feasibility of attempting to control all sources of infection, and makes the theory of isolation of all consumptives as the ultimate goal in prevention an empty dream. It should be remembered that, even if tubercle bacilli should gain entrance into the body and do not multiply no tuberculosis occurs, and if they gain entrance and do multiply and the body subsequently develops a power which prevents their further growth the disease is cured. Numerous observations of healed tuberculous lesions found in bodies dead of other diseases have been published, and show unmistakably that, in the majority of cases, the disease is cured spontaneously. The per cent. of cures so found varies with different observers and in different countries, in some instances being as high as 90 per cent. In view of these facts but one conclusion is possible, viz.: that the natural tendency of the body is to check the growth of tubercle bacilli. If the natural tendency of the body is to check the growth of tubercle bacilli, then a failure of this power is a fault of the body, and this fault then becomes the primary or fundamental cause of the disease. This method of reasoning is not new, and has been vigorously opposed, chiefly on the ground that reports showing the widespread occurrence of the disease and the findings of cured lesions have been exaggerated.

Too many reports, however, have accumulated to give this objection weight at the present time. Now if every adult over 30 years of age is tuberculous (Naegeli), and in the majority of cases the disease is cured spontaneously, the cause and prevention of the disease are presented in another light, and the burden of activity is thrown, not alone upon trying to destroy bacilli, but in trying to discover what is lacking in the treatment of those who fail to recover. The whole effort should be directed toward discovering and correcting this fault, for to correct it is to render the tubercle bacillus innocuous. It should not be thought that I am here advocating less care in preventing the entrance of tubercle bacilli into the body. Nothing could be farther from my idea. For even should the primary cause of the disease be known, and means devised for correcting it, individuals would still exist whose resistance had been lost, and who should, therefore, be protected, as far as possible, from developing the disease. My object is to show that this measure alone, if not impossible of accomplishment, falls far short of the full scope of rational preventive activities. I should mention that personally I believe the fundamental cause of tuberculosis is lime starvation, which is discussed in other papers.

Tubercle bacilli are everywhere about us, and everybody, young and old, in the usual round of human intercourse, takes them, in one way or another, into the body. It is mere vanity to believe that those who escape infection have escaped implantation. The only explanation why the whole adult world is not actively tuberculous is that in the majority of individuals the growth and development of tubercle bacilli is checked. Received in the ordinary number and way tubercle bacilli will not grow in a healthy body. It does not follow from this that the intake of an unusually large number of tubercle bacilli will not break down the natural resistance as, for instance, when an overwhelming dose is injected into a healthy animal.

Natural resistance to the growth of tubercle bacilli is a physiological power. All the powers of the body are maintained by food. The occurrence of tuberculosis at all ages, its long continuance, its exacerbations and remissions, the unexpected cures, the often rapid and surprising progress from bad to worse, are all explained on the assumption that the body alternately loses and regains some element of food essential for the normal growth and repair of tissue. If the losses exceed the gains the disease is fatal. If the gains exceed the loss the disease is cured. All grades are present from an almost equally balanced gain and loss, loss in the ascendant, in which case the disease lasts for years, to continual and extreme loss when the disease is rapidly fatal.

Rest, pure air and an outdoor life. It is evident that the general belief that rest, pure air and an outdoor life are essential agencies in the curative treatment of tuberculosis is the obstacle to be overcome in establishing systematic curative dispensary treatment in cities. That rest (for ambulant cases), pure air and an outdoor life are not necessary for the cure of tuberculosis is as certain as anything of which we have knowledge. Let us examine a few facts.

In casting about in one's mind for an example of an individual the maximum of whose time is passed in the open air of the country we naturally come upon the farmer. For at least eight, and in most cases ten months of the year, his life is spent in the open air, which in the country is pure. If pure air and an outdoor life are preventive and curative, one would logically suppose that a farmer would rarely develop tuberculosis, or, if he did, the disease would rarely prove fatal. Such is not the fact. The 1908 census reports show that in the deaths from all causes among farmers, planters and farm laborers, 8.7 per cent. were due to tuberculosis of the lungs. This does not support the logic. Farmers are freer from tuberculosis than the followers of some other occupations because the death rate for pulmonary tuberculosis reported for all occupations is 15 per cent. There can be no discussion about the healthful or unhealthful effects of various occupations. The deadly character of certain trades is proven. But why attribute the farmer's advantage to pure air and an outdoor life? If these were the factors, then miners, who spend their lives without sunlight and work in a damp atmosphere where the air is neither pure nor fresh, should show the highest mortality rate for pulmonary tuberculosis. Such is not the fact. "In the American figures miners and quarrymen, who are unfortunately associated in a single title, rank low in respect to tuberculosis to 55 years, but after that age are nearly at the top of the list. Miners appear to have a real immunity from tuberculosis, according to the English figures for all ages, and the sudden rise in mortality at 55 years may be due to retirement from this arduous occupation with advancing years." (U. S. Census, Mortality Statistics, 1909.) The mortality rate for pulmonary tuberculosis among miners and quarrymen is 8.7 per cent.

The reports of healed tuberculous lesions found in bodies dead of other diseases have before been mentioned. These reports are so numerous and so well known that it is not thought necessary to quote them in detail here.

If these statistics had been gathered from the examination of dead farmers they might be used, rightly or wrongly, as a strong argument in favor of pure air and an outdoor life. They were not so gathered. On the contrary, the examinations were made in the morgues of large cities and of large hospitals in cities. The bodies were of those who sought hospital relief in their last illness, dwellers of cities, the poorest of the poor, among whom tuberculosis is most common; the bodies of those in whom obviously rest, pure air and an outdoor life could have formed no part of the means which brought about their cure.

In explanation of these cures but one element remains, viz.: food. Probably through some happy accident of diet something was provided by means of which lost resistance was restored and the growth of bacilli checked.

Lastly, the percentage of apparent cures reported from sanatoria where the doctrine of rest, pure air and an outdoor life are practiced is far less than the percentage of apparent cures obtained at the Thompson Street Dispensary, which is situated in New York City, and where wage earners are treated without interruption to their work.

The per cent. of apparent cures reported from six well-known sanatoria, the result of treatment of patients in all stages of the disease, is as follows: Adirondack Cottage Sanatorium, 18 per cent.; Rhode Island State Sanatorium, 18 per cent.; Sharon Sanatorium, 16 per cent.; Massachusetts State Sanatorium, 16 per cent.; New Mexico Cottage Sanatorium, 34 per cent.; Loomis Sanatorium, 10 per cent. These figures give an average of 20

per cent., while at the Thompson Street Dispensary the percentage of apparent cures so far obtained, since the adoption of the lime starvation theory, is 57 per cent.

The small per cent. of apparent cures obtained at sanatoria is undoubtedly due to the fact that such institutions cannot afford to keep their patients, particularly the advanced and far advanced cases, or the patients themselves cannot afford to remain a sufficient length of time to bring about cure. While this may be a correct explanation it affords no remedy. In the very nature of things there can be no remedy for this defect. It is an unchangeable fact due to this method of treatment, and the results must, therefore, be accepted as the best obtainable under this system. On the other hand, a self-supporting consumptive can remain under treatment at a dispensary, without material disadvantage, for years.

In the reports of apparent cures from sanatoria just quoted all the incipient cases, many of whom did not show the presence of tubercle bacilli in the sputum, are included. No incipient cases are included in the Thompson Street Dispensary figures, all were advanced or far advanced in disease, and every patient's sputum showed the presence of tubercle bacilli at the beginning of treatment.

An ambulant case of pulmonary tuberculosis may be in the advanced and far advanced stage of the disease as well as in the incipient stage. Attention is called to the fact that if the cases treated at this dispensary had been selected on any ground, so far as the disease was concerned, other than that they were properly ambulant cases, and if they had consisted mainly of early stage cases, many of whom did not show the presence of tubercle bacilli in the sputum, the percentage of cures would have been much greater.

Do these apparent cures, gained under these circumstances, hold as well as those obtained at sanatoria? To answer this very important question the following comparison is made. The dispensary cases include all the apparent cures (sixty in number) since the beginning of my dispensary work March 14, 1898, up to May 20, 1906. This makes the longest period since the first apparent cure (April, 1898), more than thirteen years, and the shortest nearly six years. These patients were all treated before the adoption of the lime starvation theory. For comparison I find but one report of the ultimate results of apparent cures, viz.: Sharon Sanatorium: 79 arrested cases treated from 1891-1902, last reported upon June 15, 1907. 2.5 per cent. not heard of recently, 25 per cent. died, 72.5 per cent. still living and apparently in good health. Dispensary cases: 60 apparent cures treated from 1898-1906. 3.3 per cent. not heard from recently, 25 per cent. dead, 68.3 per cent. living and working daily, 3.4 per cent. living and not able to work.

Of the 79 arrested cases treated at the Sharon Sanatorium reviewed above, 34 only showed the presence of tubercle bacilli in the sputum at the beginning of treatment. The mild character of the disease in the remaining 45 cases, which failed to show tubercle bacilli in the sputum at the beginning of treatment, is indicated by the fact that 14 of the 18 deaths reported in detail were cases showing tubercle bacilli at the beginning of treatment. In other words, 41 per cent. of the whole number of cases showing tubercle bacilli in the sputum at the beginning of treatment died.

Of the 60 apparent cures treated at the dispensary 3 failed to show tubercle bacilli in the sputum at the beginning of treatment, and 10 were in the early stage of disease. The remainder were advanced or far advanced in disease.

The remedy for the state of affairs described in the foregoing is systematic curative dispensary treatment for all ambulant cases so arranged that the hours of attendance do not conflict with work hours. If the present sanatoria, expensive and in situations needlessly remote from centers of employment, are to be maintained their work should be restricted to the care of advanced cases with continuous fever or complications which require rest. For all other purposes they serve merely as a means of self-indulgence, which only the tuberculous rich can afford. As stated before, systematic curative dispensary treatment has been in operation for about fourteen years in New York City and its practicability proven. At the Thompson Street Dispensary the number of patients is limited strictly to fifty, and every patient is required to report twice daily in all weather, Sundays and holidays included; in the morning on the way to work and again after the last meal in the evening. The dispensary hours are 7 to 8.30 o'clock morning and evening. Once a week all patients are weighed, and the men and women are examined and notes made of their condition on alternate Sundays. Sunday is selected for weighing and examination, because it is not a work day, and, therefore, no time is lost from labor. This work requires one physician and three nurses. The nurses carry out the practical instruction* and are present at all dispensary hours. It requires but 4½ hours a week of the physician's time. Individual supervision and domination are necessary for success, hence the importance of having patients report twice daily and limiting the number to fifty cannot be emphasized too strongly. Because they are self-supporting the patients supply their food, clothing and shelter, the only expense of treatment being rent of dispensary rooms, heat, light, cleaning, salaries of nurses, etc. Based on experience at the Thompson Street Dispensary, where patients pay nothing for treatment, the average cost per patient for twelve months' treatment is about $100.

The benefits to be derived from the practical application of the idea that dispensary treatment is curative would add enormously to the value of results now obtained. If a large city like New York were dotted with such dispensaries it would quickly become known that curative treatment was to be had without interruption to work, and patients in the early stages of the disease would be stimulated to seek advice and place themselves under treatment. It would encourage and ultimately lead to systematic examination of employees, and many large stores and factories would establish their own dispensaries. The coming of patients to the dispensary twice daily disposes practically of all their leisure time, and besides giving an opportunity of thorough training in habits of personal cleanliness breaks up evil associations, if such exist. Having one member of the family in such constant, long and intimate association enables the dispensary to reach and influence the whole family.

Should a self-supporting consumptive, who can afford to pay something, be treated free of cost at a dispensary? If the answer is "no," then why not establish pay dispensaries? The expense, $8.50 a

*The necessity of fresh air, of course, is thoroughly taught.

month, could be met by many wage earners without serious inconvenience so long as they were maintained as wage earners. On the other hand, it is much cheaper for a town, city or state to treat self-supporting curable patients free than not to have them treated at all.

Comparative expense of treatment. At the New Mexico Cottage Sanatorium the average cost per patient for nine months' treatment is said by the physician-in-chief to be nearly $1,000. The yearly cost, therefore, would be $1,332. Assuming this to be the average cost of treatment at most sanatoria and the cost of treatment at dispensaries to be $100 a year, then we have the ratio 13 1/3 to 1.

These figures may be compared in a variety of ways. For instance, for every patient treated at a sanatorium, 13 1/3 patients may be treated at a dispensary; one year's treatment at a sanatorium costs as much as 13 1/3 years at a dispensary; 200 dispensaries, in any large city, treating 10,000 patients would cost $1,000,000 a year, while 10,000 patients treated at sanatoria would cost $13,320,000 a year.

But the economic bearing of this subject is not confined to the cost of treatment. Far from it. The economic value of life saving to a community depends upon the productive ability of the lives saved. How can one discuss seriously the economic value of a life-saving plan which has its widest application in the treatment of the well-to-do and the dependent and which makes no adequate provision for self-supporting wage earners?

THE ACTION OF LACTIC ACID BACILLI ON THE PERCENTAGE OF GLUCOSE IN THE URINE IN DIABETICS.

REPORT OF CASES.

By PHILIP HOROWITZ, M.D.,

NEW YORK.

Case I.—A. H., male, white, 66 years old. Native of Russia. Previous history negative as far as present condition is concerned. Family history good; father died at age of 83, and mother at age of 95. Present illness: Was in apparent good health until about a month ago, when patient began to have an intense thirst and very large appetite, anad very frequent micturition. At first he paid no attention to the condition until he noticed that his clothes became loose. Today, February 2, 1911, patient has lost about 30 pounds in weight, is very weak, badly constipated, and complains of sleepiness; claims that he has drunk as much as two gallons of water a day. General physicial examination shows beginning emaciation, marked tympanitis, and distension, otherwise negative. Urine shows traces of albumin, large amounts of indican, 4.78 per cent. glucose, and traces of acetone. I put patient on a carbohydrate-free diet and gave strong cathartics to break up obstinate constipation. The symptoms, however, became more marked and the patient slept all the time. I put patient on a liquid suspension of lactic acid bacilli February 7, 1911. Patient somewhat improved and is much brighter. Examination of the urine showed a reduction of the glucose to 2.72 per cent., but larger quantities of acetone. I allowed patient some cereal as oatmeal and rice and also white bread, and continued the suspension of lactic acid bacilli, February 14, 1911. Patient very much improved and is much brighter, is not so distended, does not drink so much, and has lost sweetish taste which he complained of. Urine shows a reduction to 2.32; no acetone or diacetic acid. Continued the suspension of lactic acid bacilli. February 26, 1911: Patient feels very well; has gained some weight and looks better. He has, however, admitted that he used cane sugar in coffee and has also eaten oranges. Urine shows glucose 1.61 per cent., and traces of acetone. Allowed patient more carbohydrate and kept up the solution of lactic acid bacilli. March 6, 1911: Patient looks very good; has gained all that he has lost; drinks very little and lives on a fairly normal diet. Percentage of glucose down to 0.65 and no acetone or diacetic acid. March 13, 1911: Feels and looks very good. Glucose 0.45; trace acetone. March 20, 1911: Patient appears normal. Glucose 0.12. March 29, 1911: Patient looks normal. Eats everything. Glucose absent. No acetone or diacetic acid. September 16, 1911: Patient in good robust health, eats everything that he was used to eating and shows no glucose or acetone, though he has been without treatment for 5 months.

Case II.—Mrs. H., 48 years old. Native of Russia; present address Wilkes-Barre, Pa. Previous and family history negative. April 9, 1911: Present history dates back to about the beginning of February of the present year. For about two months she had been afflicted with an intense itch of the genitals. Marked thirst and very frequent micturition; has lost some weight and strength and has come to New York for treatment. Examination of the urine shows 0.74 per cent. glucose and traces of acetone. Having had such remarkable results in the first case, this patient was also put on the lactic acid bacilli with a moderate amount of carbohydrates. One week later the patient sent a specimen from Wilkes-Barre, Pa. It was up to 1.55 per cent. but no acetone was present. Treatment continued. April 30. The percentage of glucose still higher, up to 1.6 per cent.; no acetone; rest of specimen fairly normal. Treatment continued May 11, 1911: The patient writes that she feels very much better. The itch has disappeared, does not drink as much and feels very well. The examination of the urine showed an absence of glucose and acetone and the specific gravity, which was always above 1030 previously, came down to 1024. Treatment was still continued and the patient was allowed regular diet. May 23, 1911: Specimen shows no glucose or acetone, but was partially decomposed, so I asked the patient to come to the city. June 6, 1911: Patient appeared for treatment. Feels much better. Looks well, but wants more to eat. She has had some liver yesterday, and would like to know whether she could continue same. Examination of urine showed glucose again up to 1.43 per cent. No acetone or diacetic acid. This high percentage probably due to the ingestion of liver for on warning patient of this no more glucose appeared in the urine. June 10, 1911: Patient feels better. Urine normal. June 22, 1911: Urine normal. Patient feels very well. September 15, 1911: Received letter from patient stating that she feels very well. Urine normal. Had no treatment the entire summer. November 25: Examination of urine negative.

Case III.—Mr. K., 50 years old, native of Germany. April 15, 1911: Has never been ill until present trouble which began two years ago. He is a very heavy beer drinker and uses tobacco excessively. For the past year or more he has been losing flesh and strength, thinks he has lost about forty

pounds, is very weak, and finds it hard to get around. He claims he has become so thin that he cannot sit down for any length of time unless he sits on an air cushion. He has an intense thirst and has very frequent micturition, or, as he expresses it, "he has to live in the lavatory." He has been a conductor on the street cars but is unable to do any work now. An examination of his urine showed 5.8 per cent. glucose, traces of albumin, large amounts of indican, and an occasional hyaline cast. Patient was put on the suspension of lactic acid bacilli and a fairly strict diet and was told that he must abstain from beer entirely. April 19, 1911: Patient does not think he has to drink as much, micturition is positively less, but claims he cannot give up his beer entirely. Still drinks between eight and ten glasses of beer a day. Complains also of sleepiness. Urine shows 4.9 per cent. glucose and traces of acetone. Same treatment continued. May 30, 1911: Patient feels better and looks better. Is very much brighter and is able to get around a little. Has stopped the beer. Urine now shows only 3.78 per cent. glucose and no acetone. May 17, 1911: Patient believes that he has gained some weight, but has pains in the lower extremities and general weakness. Urine shows 3.65 glucose. Trace albumin, no acetone. Was allowed orange juice and baked potato, treatment same. May 28, 1911: Pains in lower extremities much less. Looks much better. Does not know whether he has gained much weight. The percentage of glucose still getting lower. Now it is 2.12 per cent. Same treatment. June 10, 1911: Patient very much better. Has very little pains now. He thinks he will be able to go to work soon. Has put on some weight. Allowed him a more liberal diet. Gave him cereals and a little brandy twice daily. Same treatment. September 12, 1911: I did not see patient the entire summer. But he has continued to take the suspension of lactic acid bacilli. Feels very well. Has attended to his work for the past eight weeks. He has gained considerable weight and eats almost everything. The examination of urine shows only a trace of glucose. And then only it becomes apparent on standing for some time. Treatment still continued. September 28, 1911: Patient is gaining at the average of about one to one and a half pounds per week, and feels as well as ever. Is on the cars from 7 A.M. until about 7 P.M. without any inconvenience or trouble. Urine shows only faint traces of glucose.

Judging from the foregoing cases, and from results I have obtained in other cases since the above were reported, I believe that in lactic acid bacilli we have a preparation which acts potently in the reduction of the percentage of glucose in the urine. But my experience has been too limited to warrant the assertion that the same results can be obtained in every case of glycosuria.

32 West One Hundred and Fifteenth Street.

ENVIRONMENT IN THE TREATMENT OF NERVOUS DISORDERS.

By HANSELL CRENSHAW, M.D.,

ATLANTA, GA.

NEUROLOGIST TO THE WESLEY MEMORIAL HOSPITAL.

Honest and thoughtful neurologists will probably admit that three-fourths of the nervous people who come under the specialist's care are restored to health not by any special skill, knowledge, or medication, but simply by the advantage of several weeks' residence in a suitable sanatorium. If etiology be considered in its broadest aspect it will be seen that the basal cause of all disease is unsuitable environment. But this cause is more directly operative in relation to disorders of the nervous system than in relation to disorders of other systems. Perfect harmony between the organism and its surroundings—climatic, social, esthetic, and so on—is health; partial lack of such harmony is disease; and total loss of it is dissolution, or death. If an individual, healthy at birth, could be shielded like Rasselas from contact with any but the most suitable of friends, food, and influences, he would never suffer from neurasthenia, epilepsy, or many other diseases, however undeveloped his character might remain.

Even heredity is dependent upon environment. For, if our ancestors had not encountered surroundings having an adverse effect upon their nerves, we would not have inherited from them the neurotic tendencies which here and there render us unable successfully to cope with the ordinary exigencies of life. Considering the fundamental importance of providing suitable environment for the sick, and particularly the nervous sick, it is astonishing how we, as a profession, have neglected to recognize environment as a definite therapeutic measure of prime importance. After carefully scanning the indices of a number of such representative works as Osler's "Practice of Medicine," Forscheimer's "Treatment," and Church and Peterson's "Neurology," I fail to find the word "environment" in the index of any of them. There has existed, of course, from time immemorial the practice of prescribing climate—a mountain climate for consumptives, a sea-level altitude for nervous folk, or a change of scene for victims of worry or overwork; but the great principle which I am here endeavoring to emphasize—the principle that difficulties of environment are directly responsible for the onset and continuance of many nervous diseases—seems not to have been grasped and systematically applied.

The following are some of the environmental difficulties which are responsible for various forms of nervous disease: (1) Association with persons of unsound mind may so prey upon a sensitive individual as to create in the latter delusions, hallucinations or actual insanity. Even association with persons of great eccentricity may result in damage to young and impressionable persons. Moreover, association with nagging, menacing, or wholly uncongenial business associates or relatives is often enough to bring on functional neuroses and psychoses of almost any sort. (2) An environment enforcing much solitude or great monotony may induce, in the first instance, psychoses, and, in the second instance, nervous fatigue of grave degree. An illustration of the effect of loneliness is seen in the insanity resulting in prisoners from solitary confinement. (3) An environment involving overwork or worry is calculated to bring on nervous and mental disorders ranging all the way from occupation neuroses, through neurasthenia and hypochondria, to exhaustive psychoses and manic-depressive insanity itself. In many instances, too, there exist unseen difficulties in the surroundings of our patients—difficulties arising out of "associations" in the environment which act as reminders of bygone sins, losses, or crises of perturbing proportions.

Thus, we see that the influences calculated to upset our patients and keep them upset are varied, subtle, and complex. And we should bear in mind

that seldom are the disturbing factors single, the rule being rather that many such factors work together. I am convinced that the chief element for good in the Weir Mitchell rest cure is the isolation element. When a patient takes the rest treatment in strict form, he is as absolutely isolated from friends, relatives, and the outer world as if he had smallpox. He is neither permitted to receive mail nor to read newspapers. He lies day after day and week after week upon his bed in a quiet room, ministered to by an undemonstrative nurse. In a word, he enjoys the most simplified environment conceivable. And I firmly believe that the unmistakable and permanent benefits which have made the rest cure justly famous are chiefly due to the simple and easy life which it insures to the patient.

While I am convinced that simplification of environment, such as the rest cure makes possible, is the greatest single measure for the relief of the majority of so-called functional nervous diseases, nevertheless there is an added advantage from the mere change of environment involved. In this way we can readily see how difficult it is for even the most capable of physicians to obtain the results in the treatment of nervous people that can be obtained by the specialist who furnishes the advantages not only of a change of environment for the patients coming to him, but also of the magic influence of sufficiently simple and suitable surroundings to give nature an opportunity for restoring nervous and psychic equilibrium in the truly marvelous fashion which is her own.

In conclusion I wish to condemn the notion that the rest cure may produce permanent good if applied only for a short time. It should not be shorter than eight weeks. To those who object to the expense and inconvenience of so extended a treatment the answer is that the end justifies the means. For the relief of neurasthenia proper, major hysteria, and hypochrondria—the psychroneuroses which include three-fourths of all the sufferers from nervous disease—nothing equals nature, and the only way to bring nature to bear is to isolate the patient in a suitable manner for a suitable length of time.

1027 Candler Building.

CASES OF IMPERFORATE ANUS AND MALFORMED RECTUM.

By C. P. FARNSWORTH, M.D.,

Chamberlain, S. D.

Two cases of imperforate anus and malformed rectum in girl babies have come under my observation. The first case, that of a child three years old, who had been passing the fecal matter from the vagina since birth, was brought to us by Dr. Gauger of Chamberlain, S. D., four years ago. The child was anesthetized in order to make a thorough examination. The place where the anus should be was marked by a stellate white colored spot. The vagina was dilated slowly in order to make an examination of the opening of the rectum into it. The vagina was found to be intact, the uterus was well dilated, and the rectum was found opening into it by the left upper fornix, where the left Fallopian tube normally opens into the uterus. The child was in normal health otherwise, well nourished, and intelligent. We came to the conclusion that the case was beyond our skill. Should there be anyone who has devised and executed a successful operation for a case of this kind we should be glad to refer the case to him. The parents are poor, so the case would be practically a charity one.

The second case was that of a baby three weeks old referred by the parents in October, 1911. The child seemed normal in every other way except for the complete absence of the rectum or of any spot marking it. The fecal matter was discharging from the vagina regularly. I advised the parents to wait until the child was older before any operative interference should be attempted.

While imperforate anus is quite a frequent malformation, there is but little literature that has come under by observation with reference to it. There are several forms of imperforate anus: Entire absence of the anus; abnormal narrowing of the anus; partial occlusion of the anus; absolute occlusion of the anus, and anal opening at an abnormal point. The malformations of the rectum are: Rectum entirely absent; rectum arrested in its descent; rectum opening into some other viscus; rectum and anus normal except that the ureter, bladder, vagina, urethra, or uterus opens into it. The variations in form and the situation of the large intestine are greatly influenced by the torsion and secondary growth of the early gut tube. The most pitiable of these cases are those of girls who are otherwise normal, whose malformations belonging to the third and fourth classes render them subject to humiliation.

The Hemorrhagic Diathesis.—H. Pribram points out that quite similar clinical pictures belonging to this group may be evoked by the most diverse causes. He reports a fatal case of peliosis rheumatica, of septic origin, beginning with slight manifestations but ending fatally. He also reports a case of hemorrhagic disease arising in a pregnant woman as the result of a traumatism, with stormy onset, but rapidly subsiding.—*Prager medizinische Wochenschrift.*

Sclerosis of the Rectouterovesical Fascia.—J. Oliver states that this is a disorder of some importance, since it is commonly a cause of infertility and even of sterility, as well as a not infrequent cause of dyspareunia. It resembles Dupuytren's contraction of the palmar fascia. Sometimes the fascia is more or less thickened and contracted merely, but often it presents nodulations. It is not an inflammatory change, and it seldom, if ever, involves the mucous membrane of the vagina. The fibrous tissue causing the contraction is a very coherent fibrillar tissue like tendon tissue. It is not dependent upon any traumatic influence, but is probably due to some bacterial product absorbed from the vaginal canal and circulating in the blood. It is a derangement which may appear at any time during the reproductive life of the woman after the age of twenty-one.—*Edinburgh Medical Journal.*

Spread of Infection from Tuberculous Cervical Glands.—A. L. Turner states that as to the manner in which the tubercle bacilli pass from the cervical glands to the lungs two explanations have been offered: first, by way of the deep efferent cervical lymph vessels discharging into the thoracic duct upon the left side of the neck, and on the right side through the right lymphatic duct into the large veins, thence by the right side of the heart and pulmonary artery to the lungs; secondly, by an extension of the inflammatory process from the diseased inferior deep cervical glands directly to the pleura and apex of the lung. Experimental evidence has been brought forward in support of the extension of the tuberculous disease by the first or anatomical pathway, but the author has failed to bring forward pathological post-mortem data in support of direct extension from the cervical glands to the apex of the lung.—*Edinburgh Medical Journal.*

THE DIAGNOSTIC SIGNIFICANCE OF ABDOMINAL PAIN IN CHILDHOOD.

THE frequency with which abdominal pain occurs as a "presenting symptom" in early life and the extreme importance during this same period of making a timely diagnosis of and prompt operative interference in acute appendicitis impart perennial interest to the discussion of the differential diagnosis of abdominal pains. The "stomachache" of the small child no longer suggests to the laity even the suspicion of overindulgence in green apples, but at once conjures up the specter of appendicitis. H. Finkelstein in the *Zentralblatt für Kinderheilkunde*, January, 1912, presents a clear exposition of this subject, reviewing in a most refreshing manner the multiplicity of conditions that may underlie the expression of this most common symptom.

Leaving out of consideration those cases of acute appendicitis which present a typical and easily recognized clinical picture, the author at the outset alludes to those children who for a long time complain of abdominal pain, sometimes continuous, though varying, and sometimes occurring in attacks of a colicky nature, while vomiting very seldom and fever never occur. The question to be decided in these cases is the following: is one dealing with a case of appendicular colic with the possibility of an invasion of the peritoneum lurking in the background, or are the pains of different origin and of generally harmless import? In all of these cases the signs in the ileocecal region are either negative or inconclusive. Even if the little patient complains of pain in the lower right quadrant of the abdomen, and even though this region may give evidence of considerable tenderness on palpation, the existence of appendicitis is not thereby proved. For it may be discovered frequently that the seat of the pain is in the skin—in other words, that a cutaneous hyperalgesia, generally widespread and extending around to the back, may be present. This is one of the sensitive cutaneous areas now generally recognized as Head's zones. In the case of intestinal diseases these hyperalgetic areas are present in the abdomen and loins and always include the cecal region. The same area may be common to a number of different intraabdominal conditions: disease of the small or large intestine, constipation, diarrhea, and ulceration. Tenderness in the appendicular region does not, therefore, signify solely the presence of appendicitis.

The neuralgia secondary to a caries of the lumbar vertebræ must not be forgotten as a possible cause, while the abdominal pain that may even be localized in the right iliac region and may be accompanied by muscular rigidity, occurring as an early manifestation in pneumonia, is so generally recognized as to require no further comment. Cases that are fairly common are those of fermentative dyspepsia, not merely the pronounced forms with diarrhea and intestinal irritability, but also the lighter forms with symptoms that are not characteristic and that require further analysis. The pains in these cases are moderate but are frequently repeated, while tenderness on pressure is easily evoked the entire length of the colon. The stools, of which there are two or three daily, although sometimes only one, are lighter and softer than normal, have a sour odor and acid reaction, have a tendency to form gas, readily undergo fermentation, and contain considerable starch. By restricting the carbohydrates in the diet the fermentation is arrested and with the occurrence of formed and alkaline stools the pains do not return.

Naturally provocative of severe colic is constipation which, in some children, as the result of bad training and psychic inhibition may reach such a degree of severity as to present the syndrome of ileus—pain, enterospasm, and vomiting. These cases are to be differentiated from cases of appendicitis in constipated children by the presence of visible and palpable peristalsis. It is not generally known, but it has been definitely established, that abdominal pain may occur without any obvious cause in neuropathic children. The attacks may appear suddenly while the child is in the midst of play, but they soon pass over. There may be several attacks daily, or they may be days apart or at longer intervals. Vomiting occurs only exceptionally. Most of the patients have a diastasis of the recti, and commonly manifest neuropathic stigmata such as the facialis phenomenon, vasomotor excitability, etc. Treatment by suggestion, such as the application of a plaster, vibratory massage, faradization, frequently results in a spectacular cure. The explanation of the origin of the pain in this class of cases is a difficult one. Possibly abdominal ptosis or enterospasm may be the causative factor. In a few cases of abdominal pain there may be discovered minute hernias of the linea alba. In all of Finkelstein's cases of this nature the pains eventually disappeared, even though no treatment had been directed against the hernia. Occasionally the cause of abdominal pain may reside in an intestinal stenosis. A pronounced degree of stenosis presents symptoms identical with those of appendicular colic. In the milder cases there is a slight meteorism, vomiting is absent, the general condition of the child is good, and only the attacks of pain indicate a grave intraabdominal condition. In these cases the clue to diagnosis is furnished by a slight spasticity of the intestine. In the long run all of these children get better. There must be borne in mind, however, the possibility of intestinal obstruction caused by peritoneal new growth, usually of a

circumscribed tuberculous character. It need hardly be mentioned that the various other causes of abdominal pain which operate chiefly in adult life are also present, though to a minor degree in childhood. The presence of calculi in various parts of the genitourinary tract is a not infrequent cause of abdominal pain in early life.

The important point emphasized by Finkelstein is that localized pain and tenderness in the ileocecal region are not necessarily an indication that appendicitis is present.

CROWN-GALL AND HUMAN CANCER.

Crown-gall is a disease, so-called because it injuriously affects the crowns of trees and shrubs, but as it occurs also on roots and shoots, its appellation is somewhat of a misnomer. Dr. Erwin F. Smith, U. S. Department of Agriculture, discusses this plant disease (*Science*, February 2, 1912), and traces certain resemblances between it and human cancer.

The resemblance between overgrowths on trees and shrubs and human cancer has been frequently pointed out. This resemblance is ingeniously sketched by the author. The article, however, is too long, and the description of both crown-gall and human tumors of a malignant type is too intricate to be more than referred to. In the first instance the author asserts that crown-gall is a true tumor. The most striking point of likeness between the plant tumor and human cancer noted by the author was that in both the cell itself is a disturbing force.

The following supposition concludes the article: "Suppose we had in human cancer as its cause a microorganism multiplying in small numbers within the cell, having a definite action on cell nuclei, readily inhibited by its own by-products, losing virulence easily, passing quickly over into involution forms, which are difficult to stain, and which are so paralyzed that only a very small portion will grow at all, except from the very youngest cells, and these only after a considerable period of time has elapsed; and further, suppose that for their growth some very special technique of isolation, or some peculiar kind of culture media were necessary, then we should have precisely the same difficult conditions of isolation and determination as have confronted us in case of this similar overgrowth of plants, and ample explanation of why expert animal pathologists have been unable to see the parasite in their sections, and unable to cultivate it on their culture media, and consequently have very generally reached the conclusion that it does not exist. Granted the existence of such an organism, and we have a ready explanation for the growth of the cancer cell in defiance of the physiological needs of the organism. The hitherto inexplicable occasional change in the nature of the cell growth of tumors, that is, from epithelial to carcinomatous, and from carcinomatous to sarcomatous, also finds its explanation in the presence of a sensitive microorganism growing usually in the kind of cell originally infected, but capable under certain circumstances of invading other types of cells."

CREMATION

Cremation of the dead was practised generally by ancient nations with few exceptions. In Egypt bodies were embalmed. In Judæa they were buried in sepulchers. In China, earth burial was the custom. The Greeks, Romans, Slavs, Celts, and Germans burned their dead. Only suicides, unteethed children, and persons killed by lightning were denied the right to be burned in Greece. With regard to modern cremation Italy was the pioneer country. It was first proposed to adopt cremation in Italy in 1866, and the first cremation of a human body in a closed receptacle took place in Milan in 1876. In 1877 cremation was rendered legal in Italy. In Berlin, Leipzig, and Dresden there has been strong agitation in favor of cremation. In the United States cremation is more frequent than in any land. The British Cremation Society was established in 1874. Sir Henry Thompson, the great surgeon who operated on Napoleon III, was a firm upholder of cremation, and was the first president of the British Society.

The reasons for and against cremation have been discussed often, but it may not be out of place briefly to recapitulate them. When the population of the world was sparse and cities few, earth burial presented no grave disadvantages. Now it is a different matter entirely. Churchyards in the midst of crowded cities or cemeteries situated in populous suburbs are contrary to the laws of health. Without exaggeration they may be said to be a menace to the health of the community. Such is obviously the case when persons die from a virulent infectious disease. Indeed, the burial of those who die from plague is believed to be a distinct source of danger. According to many who have written on the subject earth burial of those who have died from diphtheria, scarlet fever, smallpox, typhoid fever, and cholera is to some extent a dangerous custom.

The objections against cremation are religious and medicolegal. The contention is made that burning bodies tends to destroy evidence of crime, and thus to facilitate the escape of criminals. But nobody ought to be cremated without independent certification as to cause of death by two physicians, or if there is then any doubt an autopsy should be made. As for the religious aspects of the matter, the greatest antagonism on the part of some Christian bodies is because of the doctrine of the resurrection of the body, and partly on account of the notion that the Christian dead body is redeemed and purified, a temple of the Holy Ghost. Nevertheless, several saints have been burned, and in reference to bodies it may be pointed out that the earthly body is but a husk. In the words of a part of the burial service "there is a natural body and a spiritual body." The spiritual body, it is taught, never dies, and it is a matter of small moment what happens to the earthly tenement.

From the sanitary standpoint the advantages of cremation are so obvious as to require no elaboration. The custom may upset long-held views, tradition, and sentiment, but from the public health point of view the arguments in support of it are unanswerable

Aberrant Thyroid and Thyroid Metastases.

A year or two ago a distinguished surgeon removed a clinically malignant growth from the occipital bone, and the pathologists to whom the tumor was submitted pronounced it an "aberrant thyroid." There was no question as to the general competence of the pathologist, and none of the medical men who learned of the diagnosis offered any criticism as to the propriety of the term employed. Nevertheless, there is, or should be, a very clear distinction between an aberrant thyroid and a malignant thyroid metastasis to bone, such as occurs in cases of simple goiter and even at times in connection with an apparently healthy thyroid. This is none the less true, even if it is possible for an aberrant thyroid to undergo malignant degeneration. An aberrant thyroid is practically the same thing as an accessory thyroid, and despite the local varieties of the latter their limits are definitely fixed. At a recent meeting of the Berlin Laryngological Society (*Berliner klinische Wochenschrift*, October 23) two men reported cases of this sort—one was retropharyngeal in site, the other retrosternal. Accessory thyroids could hardly be accounted for outside of such limits, for they should have a purely embryonal origin from misplaced embryonal tissue. In no sense can such formations be termed metastases, nor do they possess any natural tendency to malignancy. On the other hand, malignant growths having the intimate structure of the thyroid gland have often been found in the bones and especially in the vertebræ, which is the common localization. It is not surprising that now and then such growths occur in the cranial bones, especially in the occipital region. This relative proximity to the thyroid region is, of course, a pure coincidence. Despite the usual dependence of these tumors on some neoplastic alteration in the thyroid, the latter is not necessarily affected, and for all practical purposes the growths may as well be regarded as primary or essential sarcomata of bone—at least, this would be the diagnosis if the microscope were not available. The case collectors of thyroid bone metastases do not even mention aberrant thyroid in their articles, so fundamental is the distinction between the two affections.

Etiology of Cancer of the Female Genitals.

It has been the general experience that while the etiology, or rather the exciting cause, of superficial cancer is tolerably evident, we are correspondingly ignorant of the causal factors of deep-seated cancer. The very terminology of epithelioma is often suggestive of the causation—smoker's cancer, soot cancer, paraffin cancer, etc., etc., but it would require a prolonged search to find corresponding titles for carcinoma of the viscera, or even for many growths which are of superficial site but not superficial in the technical sense, as scirrhus of the breast. The day is doubtless not far off in which we may be able to group all cancers according to leading determining factors. At least we get that impression from a paper read by Theilhaber last month before the Gynecological Society of Munich (*Münchener medizinische Wochenschrift*, December 12, 1911). It is not that he tells us anything actually novel, but he parades the determining causes of great numbers of cancer in such a way that our conception of their nature is intensified and the question of prevention and cure brought home in a pointed fashion. Cancer of the cervix is practically a "scar cancer," he states. A great deal of cancer of the tubes and corpus uteri might be termed "gonorrhea cancer," because the latter develops as a result of chronic endometritis and salpingitis, due originally to the gonococcus. We also have a "climacteric cancer" and a "senile cancer." There is also an "operation cancer," which is necessarily a recurrence due to inoculation. It becomes painfully evident that the same woman may be exposed to the danger, not only of one, but many, genital cancers.

News of the Week.

Smallpox on the Cedric.—The White Star liner *Cedric*, which arrived on February 28 from the Mediterranean, had on board a case of smallpox among the cabin passengers. The victim was Henry Hayden Sands, the young aviator, who recently distinguished himself by flying over the pyramids.

Automobile Injuries.—Eleven persons were killed and fifty-seven injured by motor vehicles, exclusive of trolley cars, in the streets of New York during the month of February. In two years 263 deaths in this city have been due to that cause. The number of fatalities shows a nearly continuous increase from month to month in the past three years.

Accidents on Street Railways Fewer.—In New York City only 15 persons were killed on the transportation lines during the month of January, according to the report of the Public Service Commission. This is the lowest death toll in any month since the commission began to keep records on July 1, 1907. The total number of accidents during the month was 5,448, and although there were 3,348 persons injured, the number whose injuries were serious was only 170.

Fatalities in Train Wrecks.—According to the bulletin issued by the Interstate Commerce Commission, there were 201 persons killed and 4,283 injured in train accidents during the months of July, August, and September, 1911. This was a decrease of 120 killed and an increase of 391 injured as compared with the corresponding quarter of 1910. Accidents of other kinds on railroads at grade crossings, on tracks, bridges, etc., brought the total number of casualties up to 2,758 killed and 19,107 injured for the quarter, a decrease in the number for the corresponding quarter of the previous year. During the quarter 131 employees of railroads were killed and 23,650 injured in accidents on railroad premises.

Infant Mortality Remains Low.—A bulletin issued by the New York Department of Health shows that for the week ending February 24 there were 258 deaths of babies under one year of age as compared with 309 for the corresponding week of last year. The total number of deaths of infants under one year of age since January 1 amounts to 2,035, as compared with 2,137 for the same period of last year. During this week there were 23 deaths of babies under one year of age from diarrheal diseases as compared with 50 deaths from the same cause in the corresponding period of 1911. The Department of Health now has 33 milk stations opened, 19 in Manhattan, 2 in the Bronx, and 12 in Brooklyn, with a total of 3,011 babies in attendance.

Straus Milk Laboratories Incorporated.—The

Nathan Straus Pasteurized Milk Laboratories, with a principal office in New York City, was incorporated on February 29 for the purpose of establishing milk depots throughout the State, where they will furnish pasteurized milk free or at cost price with the view of reducing sickness among infants.

Saccharin Declared an Adulterant.—Basing their conclusions on the report of the Remsen board of consulting scientists which has conducted investigations into the effect on health of the use of saccharin, Secretary Wilson of the Department of Agriculture, Secretary Nagel of the Department of Commerce and Labor, and Secretary MacVeagh of the Treasury Department, have ruled that on and after April 1 next foods or drugs which contain saccharin will be regarded as adulterated by the Pure Food and Drugs Board and the manufacturers will be prosecuted.

Teach Preventive Medicine Through the Newspapers.—The Georgia State Board of Health, believing that a series of short newspaper letters dealing with sanitation and health subjects will appeal to the people of Georgia, has inaugurated a press service which will be offered to every newspaper in the State.

Scarlet Fever in North Haven, Conn.—Scarlet fever is epidemic in North Haven, Conn., there being about fifty cases of the disease in the town. A dance given in a public hall is supposed to have been instrumental in spreading the disease, as many of those who attended were soon after stricken with scarlet fever.

Cold Storage Turkeys Cause Ptomaine Poisoning.—Twenty cold storage turkeys served at a dinner of the Men's League of the Reformed Church of Belleville, N. J., have been the cause of many cases of ptomaine poisoning. Eight of the sufferers were reported as being in a serious condition.

New York's Death Rate Continues Low.—The death rate for Greater New York for the week ending February 24 was 16.49 per 1,000 population, while for the corresponding week of 1911 it was 17.48. There were eight deaths from typhoid fever which was double the number for the corresponding week of 1911, and 37 more deaths from ear disease. There was an increase of 11 deaths from tuberculosis and a decrease of 14 from pneumonia. Bright's disease and nephritis caused 118 deaths, which was 12 less than for the corresponding week of last year. The deaths of children under five years of age numbered 400, of which 258 were under nine years of age. Almost one-fifth of the number of deaths were among persons over 65 years of age.

Resuscitation from Electric Shock.—The meeting of the Commission on Resuscitation from Electric Shock was held in the board room of the National Electric Light Association on February 22. This commission has for its purpose the study of electric shock and the preparation of a set of rules for first aid in cases of electric accidents. The commission is composed of members of the American Medical Association, National Electric Light Association, and American Institute of Electric Engineers. The members nominated by the American Medical Association are: Dr. W. B. Cannon, professor of physiology, Harvard University, chairman; Dr. George W. Crile, professor of surgery, Western Reserve University; Dr. Yandell Henderson, professor of physiology, Yale University; Dr. S. J. Meltzer, Rockefeller Institute of Medical Research, New York; Dr. E. A. Spitzka, professor of general anatomy, Jefferson Medical College; Mr. W. D. Weaver, editor of the *Electrical World*, secretary. The member nominated by the National Electric Light Association is Mr. W. C. L. Eglin, electrical engineer of the Philadelphia Electric Light Company. The members nominated by the American Institute of Electric Engineers are: Dr. Elihu Thomson, electrician of the General Electric Company; Dr. A. E. Kennelly, professor of electrical engineering, Harvard University. The medical members unanimously advocated the Schäfer, or prone, method, as the best means in the hands of laymen for maintaining respiration in victims of electric shock, and the commission formally voted to recommend this method. A chart is being prepared which will give details of first aid in cases of accidents from electricity and will describe fully the method of applying artificial respiration. This chart is being issued by the National Electric Light Association.

The Committee on Prevention of Blindness of the New York Association for the Blind, in its annual report, states that the census of blind pupils in the United States, as compiled by the committee, shows that there are 2,018 in seventeen schools, 25 per cent. of which were blind as a result of ophthalmia at the time of birth. In their efforts to find out in how far local health officers were able to provide immediate and adequate medical care for cases of ophthalmia, they found that there was need of further provision for such care, although to what extent it was not possible to determine. Investigations in the hospitals and dispensaries of New York show that the disease prevailed much oftener than was generally believed and that the law requiring that redness and swelling of the eyes in the newborn be reported within two weeks after birth to the Board of Health was not generally obeyed. It is hoped that through this investigation and the prosecution of gross cases of neglect with attendant publicity that the law will be enforced and every case reported to the Board of Health. It is hoped that each case reported will be followed up by a competent nurse as in Boston, where, as the result of a campaign of publicity, the number of cases reported has increased from 10 in the month before the first conviction was made to 160 eight months later. Since this follow-up system has been adopted not one case has resulted in blindness. Sets of questions sent to the teachers in the public cities in New York elicited replies from principals indicating that 8.05 per cent. of the 11,280 children examined were suffering from some form of defective vision, and the general impression gained by this study was that a careful and scientific examination of school children's eyes was desirable, and that if the result of such an examination should corroborate the figures quoted above special classes would be desirable for children with seriously impaired vision. The report also states that much blindness is caused by wood-alcohol poisoning.

Protest Against the Health Department's School Inspection.—At the February meeting of the Kings County Medical Society, resolutions were passed protesting against the employment by the Health Commissioner of nurses in the diagnosis and treatment of disease in children of the public schools, and also against the establishment of dispensaries for the treatment of defects in school children.

Nurses Revise Their Charges.—The organized nurses in New York have decided on a flat rate of $4 per day instead of the weekly rate of $25. The reason for the change is given as the increased cost of living and the frequent misunderstandings between patient and nurse as to the proper charge for a part of a week.

Women Physicians Try for Ambulance Service.—At the examinations held on February 29 to fill positions in Bellevue and the Allied Hospitals four women were permitted to take the examinations for the ambulance service; one passed successfully.

Endeavor to Make Central American Ports Sanitary.—The United States Fruit Company is making preparations to maintain a medical department for the purpose of making all Central American ports as sanitary as those of Panama and to supervise the hospital and general sanitary conditions throughout the country. Dr. R. E. Swigert will be the general superintendent of the medical department with offices in New Orleans.

Texas Physicians Want State Medical Board Appointed.—The Texas State Medical Society is preparing a bill to be presented at the next session of the Legislature asking that a State Medical Board consisting of seven members be appointed by the Governor, the board to be composed of all schools of medicine.

Dr. Thomas W. Salmon has resigned his position as chairman of the New York State Board of Alienists. Dr. Salmon, who was granted leave of absence without pay by the United States Public Health and Marine Hospital Service for one year to take up his work in the Board of Alienists, has had the leave extended so as to permit him to make some studies regarding the care of the insane in the United States which will be undertaken by the National Committee for Mental Hygiene.

Dr. Eugene Du Bose Bondurant has been elected dean of the medical department of the University of Alabama, to succeed Dr. Rhette Goode, deceased.

Dr. D. J. Donahue of Glendive, Mont., has been elected President of the State Board of Health.

Dr. Fritz B. Talbot of Boston has been named as consulting physician of the newly created pediatric department of the Union Hospital of Fall River, Mass.

Dr. James R. Hayden, professor of genito-urinary surgery at the College of Physicians and Surgeons, New York, was operated on for appendicitis on March 2 at his home.

Dr. Horace David Arnold has been appointed dean of the Harvard Medical School to fill the place made vacant by the resignation of Dean Henry A. Christian.

Prof. Edward Hickling Jackson, professor of orthopedic surgery at Harvard University, and Professor James Jackson Putnam, professor of diseases of the nervous system, have been made professors emeritus.

Dr. Charles S. Minot, James Stillman professor of comparative anatomy at Harvard Univerity, has been appointed exchange professor at the University of Berlin for next year. His subject at the German university will be embryology. This is the first time that a member of the medical faculty of Harvard has been appointed as an exchange professor.

Seaside Homes for Crippled Children.—A nation-wide movement for the care and treatment of crippled and convalescent children has been inaugurated through the efforts of several well-known women of New York and Brooklyn. The movement has in view the establishment of a chain of homes along both the Atlantic and Pacific coasts where children may be taken from inland cities. Branches of the organization have already been started in many of the large cities and several homes are now in operation. Among the members of the advisory board are Dr. Henry Ling Taylor, State Comptroller; William H. Sohmer, John C. Fitzgerald, Andrew T. Sullivan, and Magnus Gross, president of the New York Teachers' Association.

Favor Continuance of Columbia and Emergency Hospitals.—The committee appointed by the Board of Trade of Washington, D. C., to reconsider the action recently taken to abandon the Columbia Hospital has decided that it would be advisable for the Government to continue to aid the Columbia and Emergency Hospitals, and has urged an appropriation of $200,000 for the construction of a municipal hospital. The report urges an appropriation of $300,000 for the erection of a new building for Columbia Hospital, and $100,000 for aid in the construction of a new emergency hospital. It is understood that a minority report will be brought in by those who take the position that private and governmental charities should be distinct, and that a municipal hospital should be erected to care for all charity work for which the Government pays.

Beth-Israel Hospital to Be Enlarged.—The annual report of Beth Israel Hospital, which is located on the lower East Side of New York, shows that during the year 1911 there were 1,948 patients who received treatment, while 2,047 were rejected because of lack of hospital accommodations. It was announced that the building fund of the hospital now amounts to $198,000, but the question remains undecided as to whether it would be better to enlarge the present hospital or to build a much larger institution elsewhere.

Babies in Brooklyn Hospital Poisoned.—A maid of all work has confessed to having poisoned eight babies in the Infants' Hospital of the Brooklyn Nursery by placing oxalic acid in the milk bottles. Four of the babies have died, and it is believed that four will recover. It is the belief of the hospital authorities that the perpetrator of this crime is insane.

Charitable Bequests.—Among the beneficiaries of the will of Harriet Demuth are the following: Mount Sinai Hospital, $1,000; Home for Aged and Infirm Hebrews, $2,000; Montefiore Home, $1,000; New York Society for the Improvement of the Poor, $1,000; Visiting Guild for Crippled Children, $2,000; German Hospital, $1,000.

The Fourth District Medical Society, which met at Columbus, Ga., on February 20, elected the following officers: *President*, Dr. H. J. Goodyear of Roopville; *Vice-President*, Dr. Martin Crook of Columbus; *Secretary-Treasurer*, Dr. Homer Boatwright of Carrollton.

The Lavaca County Medical Association, which met at Yoakum, Tex., on February 17, elected the following officers: *President*, Dr. J. F. Lay of Hallettsville; *Vice-President*, Dr. A. M. Kotzebue of Moulton; *Secretary-Treasurer*, Dr. W. Shropeshire of Yoakum; *Delegate to State Medical Association*, Dr. A. M. Kotzebue.

The Tri-State Medical Society, which met in

Columbia, S. C., on February 22, elected the following officers: *President*, Dr. A. E. Baker of Charleston, S. C.; *Vice-Presidents*, Drs. A. B. Knowlton of Columbia, S. C.; A. J. Crowell of Charlotte, N. C., and A. L. Gray of Richmond, Va.; *Secretary-Treasurer*, Dr. R. E. Hughes of Laurens, S. C.; *Members of Executive Council*, Drs. R. B. Epting of Greenwood, S. C.; Southgate Leigh of Norfolk, Va., and J. H. Wey of Waynesville, N. C.

The Bronx Medical Association has elected the following officers for 1912: *President*, Dr. Charles Graef; *Vice-Presidents*, Drs. Benjamin T. Tilton, and Francis L. Donlon; *Recording Secretary*, Dr. William J. Walker; *Corresponding Secretary*, Dr Arthur T. Butte, Jr.; *Financial Secretary*, Dr. Edward R. Cuniffe; *Treasurer*, Dr. Carl Wurm.

The Jackson County (Ga.) Medical Society at the first of its three annual meetings at Jefferson on February 13, elected the following officers for the ensuing six months: *President*, Dr. Lactus Sanders of Commerce; *Vice-President*, Dr. E. M. McDonald of Jefferson; *Secretary-Treasurer*, Dr. J. C. Bennett of Jefferson.

Obituary Notes.—Dr. Arthur Kendrick MacDonald died at his home in Princeton, N. J., on February 29, at the age of sixty years. He was graduated from the University of Pennsylvania in 1875, and was for many years the Princeton University athletic physician, and at one time attending physician to President Cleveland.

Dr. Robert A. Corbett, a graduate of the Medical Department of Victoria College in 1860, died at his home in Port Hope, Ontario, on January 27 at the age of 75.

Dr. Patrick H. Harriman of Norwich, Conn., a graduate of the New York University Medical College in 1884, died on February 19 at the age of 52 years.

Dr. William W. Knight of Sharon, Conn., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1853, died on February 18 at the age of 79.

Dr. Ralph Melville Mead died after a brief illness at his home in Brooklyn on February 16. He was graduated from the Long Island Medical College Hospital in 1882.

Dr. William B. Martin of Sherrard, Ill., a graduate of Rush Medical College, Chicago, in 1888, died recently at the age of 52.

Dr. W. A. Daniel of Traer, Ia., died on February 12 at the age of 87 years. He was graduated from Rush Medical College in 1852 and during the Civil War was commissioned as surgeon of the Twenty-fourth Iowa Regiment.

Dr. J. J. Williamson of Cleyburne, Tex., a graduate of the Medical Department of Tulane University, died at San Angelo, Tex., on January 26.

Dr. Joseph Lawrence Nevin of Jersey City, N. J., died of peritonitis on February 26, at the age of fifty-nine years. He was graduated from the New York Homeopathic Medical College and Hospital in 1878.

Dr. John P. Curley of Providence, R. I., a graduate of the Harvard Medical School in 1878, died at the home of his brother, the Rev. William S. Curley, in Fall River, Mass., on February 20, at the age of fifty-five years.

Dr. Fred. Nelson Burnett of Attleboro, Mass., a graduate of the Long Island Medical College and Hospital, died suddenly in Dorchester, Mass., on February 20, at the age of fifty-two years.

Dr. Wenceslas Jean Baptiste Chagnon died at his home in Fall River, Mass., as the result of a stroke of paralysis on February 22, at the age of seventy-four years. He was born in Rouville, Province of Quebec, in 1837, and was graduated from the medical department of New York University in 1860.

Dr. Joshua F. Lewis of Malden, Mass., superintendent of the adult poor of the State Board of Charities, died in the Massachusetts General Hospital of asthma and heart trouble, on February 26. He was born in Provincetown in 1855, was graduated from Dartmouth College in 1879, and from the Harvard Medical School in 1887.

Dr. Henry Nelson Winton, head of the department of chemistry in the Oakland College of Medicine, died suddenly on February 20. He was born in Haywards, Cal., in 1862, and was graduated from the medical department of the University of California in 1885, and from Jefferson Medical College in 1886.

Dr. William Smith, the first graduate from the school of osteopathy in Kirksville, Mo., died in Dundee, Scotland, on February 21. He taught surgery and anatomy in Kirksville for more than fifteen years.

Dr. George Henry Deming, a well-known veterinary of Springfield, Mass., died in the Wesson Memorial Hospital on February 24, at the age of fifty-four years.

Dr. Josiah Hamilton Goddard of Orange, Mass., a graduate of the College of Physicians and Surgeons of New York City in 1861, died on February 21, at the age of eighty-two years.

Dr. Ludwig Pauly, a graduate of the Chicago Homeopathic Medical College in 1879, died of pneumonia at his home in Milwaukee on February 21, at the age of eighty years.

Dr. John Henry Baker Denton of Freeport, L. I., died in St. Petersburg, Fla., on February 26, at the age of sixty-one years. He was graduated from the medical department of the New York University in 1871.

Dr. John W. Parsons died of pneumonia at his home in Portsmouth, N. H., on February 28 at the age of seventy years. He was graduated from Harvard Medical School in 1865, was president of the American Medical Association in 1884, president of the Stratford Medical Society in 1884 and 1889, and of the Harvard Medical Alumni in 1891. In 1865 he was commissioned assistant surgeon of the Twenty-fourth Massachusetts Volunteer Infantry.

Dr. Frederick B. Lawson of Newton, Mass., a graduate of Berkshire Medical College, a retired physician, died at his home in Acushnet, at the age of seventy-three years.

Dr. Fred N. Burney of Attleboro, Mass., a graduate of Long Island College Hospital, Brooklyn, in 1892, died suddenly of heart failure February 21, at the age of fifty-two years.

Dr. Edgar T. Newsome of Boston, Mass., a graduate of the Medical School of Harvard University, Boston, at one time superintendent of the Copp Sanatorium at Nashau, N. H., died on February 6 of typhoid fever, at the age of thirty-eight years.

Dr. Charles Robert Sanger, professor chemistry and director of the chemical laboratory of Harvard University, died at his home in Cambridge on February 25, at the age of fifty-two years. He was at one time Professor of Chemistry at the United States Naval Academy at Annapolis, and

later occupied the Chair of Chemistry at Washington University, St. Louis.

Dr. PATRICK H. HARRIMAN, a graduate of the New York University Medical College in 1884, died at his home in Norwich, Conn., on February 17, at the age of fifty-two years.

Dr. FREDERICK W. BUECHERT of St. Louis, Mo., died after a six months' illness at the Alexian Brothers' Hospital, on February 21, at the age of sixty-four years.

Dr. WILLIAM R. HITCHCOCK, a graduate of the New York University Medical College in 1878, died at his home in New York City on February 25, at the age of forty-two years.

Dr. HUGH P. KIBY, a graduate of the South Carolina Medical College in 1908, died suddenly at his home in Loris, S. C., on February 25, at the age of twenty-eight years.

Obituary.

LEONARD WEBER, M.D.

NEW YORK.

Dr. LEONARD WEBER, professor emeritus of general medicine at the Post-Graduate Medical School, former president of St. Mark's Hospital, and a well-known and highly esteemed practitioner of this city, died at his home on March 1, at the age of seventy-five years.

He was born in Bavaria, Germany, and was graduated from the University of Erlangen in 1860. Three years later he began the practice of medicine in this city. From 1867 to 1870 he was visiting physician to St. Francis' Hospital. In 1890 he was elected president of St. Mark's Hospital. In 1865 he became professor of general medicine in the Post-Graduate Medical School, a position he held until 1910, when he was elected emeritus professor. In October of that year the medical faculty of the University of Erlangen, Dr. Weber's *alma mater*, bestowed upon him a signal honor by renewing his diploma on the fiftieth anniversary of its granting, and announcement of this honor was accompanied by an appreciative letter from the president of the faculty.

Dr. Weber was a member of the New York County and State Societies, the New York Academy of Medicine, the American Medical Association, the American Climatological Society, and the National Association for the Prevention of Tuberculosis.

CHARLES BELL CONVERSE, M.D.

JERSEY CITY.

Dr. CHARLES B. CONVERSE, County Physician of Hudson County, N. J., for thirty-six years, and one of the best known medical men in the State, died on Monday of this week at the age of 70. He was born in Norwich, Vt., and was graduated from Dartmouth College in 1863. He studied medicine at the Georgetown University, from which he was graduated in 1870. He took a second degree from the Bellevue Hospital Medical School in 1871. He then served as interne for a year in the City Hospital, Jersey City. He began the practice of his profession in 1872. In 1876 the Hudson County Board of Freeholders appointed him County Physician, a position he held until his death.

LISTER—VACCINE TREATMENT OF PUERPERAL SEPTICEMIA — INSURANCE DISPUTES — MR. LLOYD GEORGE'S ATTACK ON THE ROYAL COLLEGES, ETC.—PROFESSOR ODLING—KALA-AZAR—OBITUARY.

LONDON, Feb. 15, 1912.

LISTER died on the 10th inst., in his 85th year. This was an event of universal as well as medical import which, like the rest of the world, you will have learned by telegraph. The funeral is being held today. The authorities desired that it should be in Westminster Abbey, but the family declined that honor, in deference to a wish once expressed by the deceased to be placed in the same grave as his wife. A part of the service is being held in the Abbey this afternoon, which affords the opportunity of assembling in his honor to numerous scientific and medical friends. I say nothing of his work. You know it, as do your readers, and one may say, as all the scientific and medical world. There is one feeling to mingle with that of loss. He had the satisfaction of living to see the results of his labors.

In the Section on Obstetrics and Gynecology (R. S. M.) Dr. G. T. Western gave on the 1st inst. an interesting account of an investigation in the bacteriological laboratory of the London Hospital respecting 100 cases of puerperal septicemia treated with vaccines. Some two years ago a report as to 20 of these cases was given to the Hunterian Society and they were included in the present statement. The patients were admitted to the ward set apart for such cases and drawn from the neighborhood after confinement, often in unsanitary homes. In reference to the wide differences as to what should be included in the term puerperal septicemia, Dr. Western suggested that was not in most cases a condition in which multiplication of bacteria takes place in the blood to any great extent, but rather one in which there is a local infection, around which a localizing barrier has not been set up by the tissues, so that bacteria are more or less continually being carried into the circulation, where they do not long survive unless they form an embolus or get caught in a thrombus. In such case pyemic abscess might follow. Puerperal fever then would include (1) localized bacterial infection in the genital tract with toxemia; (2) such local infection from which bacteria are carried into the blood stream, continuously or discontinuously. Group 2 comprises the true septicemias, but the two groups merge so much into each other that, clinically, they cannot be separated, and perhaps this may explain the diversity of opinion as to the mortality. A carefully arranged table of the 100 cases was exhibited. Fifty-six of them were treated with vaccines. The conclusions arrived at were (1) the mortality of cases in which there is definite bacteriological evidence of bacteria in the blood stream ranges from 85 to 95 per cent.; (2) this mortality, by inoculation with autogenous vaccines, may be reduced to about 55 per cent.; (3) among notified cases the mortality was about 60 per cent.; but (4) this could be reduced about half with appropriate vaccines; (5) if in any case the uterine cavity should be explored the opportunity of obtaining a culture at the same time should not be lost; (6) stock vaccines give inferior results and should only be used when autogenous ones cannot be obtained.

In the discussion of this paper Dr. Williamson said that in some cases bacteria were only in the blood for a brief period and practically innocuous. But when they multiplied rapidly they constituted septicemia. He would not agree that the uterus was normally sterile throughout the puerperium. He strongly favored autogenous vaccines, but to obviate delay he would use a serum *pro tem.* Dr. Inglis Parsons spoke of the difficulty of determining the state of the blood. If the opsonic index were much below normal that might be a negative phase from absorption of autotoxins, or else a normal low position of the index. In the former case an antiserum was the best treatment; in the latter a vaccine. Dr. Amand Routh held that vaccine therapy was of use when puerperal infection of the uterine mucosa was localized by exudation around it (peri- and para- metritis). But if the bacteria were in the blood they would stimulate the formation of antibodies, and the addition of more bacteria, even if dead, did not seem likely to do good. Most of Dr. Western's cases had a good chance of recovery, as they came under treatment more than ten days after infection, for severe septicemia cases generally die within ten days. Dr. Topley did not think it safe to use an autogenous vaccine in 24 hours without subcultures to ensure sterility. Nor was it of no import to introduce a few living organisms in septicemia, for they would be an unknown number in a very brief period. In his reply Dr. Western admitted that success was greatest in the less rapid cases, as might be expected. The most virulent cases would be the most difficult to save, and if he could reduce their mortality 50 per cent. in other cases, to save these would bring it to zero. The differences of opinion as to the uterus being sterile he attributed to differences of the method of taking cultures rather than to the date of obtaining them.

The lecturing campaign to persuade the people of the value of the Insurance Act has been started. Mr. Lloyd George inaugurated it by a speech at what was called a conference, but the audience was strictly partisan, admission being by ticket only, obtainable from two Liberal societies. The chair was occupied by the Liberal chief whip, who promised to instruct all his paid agents to urge that only Liberals can be credited with any benefit from "our act." Mr. Lloyd George then addressed this "conference" in which there was no pretense of conferring. He accused his opponents of "misrepresentations, distortions, falsifications, downrighters," and other iniquities, but his critics are saying he must have been enumerating his own transgressions. He charged all who asked for delay with "inhumanity," but did not tell his hearers that he had himself given his insurance commissioners full power to order postponement if they found it advisable to do so. Passing from his general to his medical critics, he poured the vials of his wrath on the latter and warned them that if they continued to oppose him their last state should be worse than the present. One of his audience, calling on me the next day, was much impressed with this, and said he was sure the profession had better hasten to make some compromise, for the Chancellor was determined to hand them over to the Friendly Societies. He told me, too, that Mr. George warned them if they refused to act the country would be covered with dispensaries. I suggested that dispensaries would require doctors, and he said he felt that while the Chancellor was talking. The climax of anger was reserved for the Royal Colleges and General Medical Council, who had declined to meet the commissioners on the ground that the "medical benefits cannot be carried out with due regard to the interests of the public and the welfare of the profession without an amending act." This Mr. George called "rude ineptitude," and declared that "no strike committee in the land would have demeaned itself" by refusing to meet a government department. He sneered at critics who thought he was so simple as not to protect himself against refusal of the doctors to work the act. Large powers of suspension were inserted in the act for that very purpose and there would be no hesitation in using them. All the safeguards of the doctors in the act would be swept away if they would find themselves in the hands of the Friendly Societies without any appeal. And it will not only be those societies as heretofore, for all the trades unions and some other societies will be with them. To them will be handed the money for medical benefits, and the doctors must deal with them.

Yesterday the presidents of the two Royal Colleges issued a reply to the Chancellor's charges. Their language contrasts vividly with his, as they leave the public to judge whether their refusal to attend the commissioners' conference is rightly described by him as "curt, undignified, and discourteous." They point out that on the introduction of the bill they informed the government how it militated against the profession, but the act shows how little attention was paid to their suggestions. But the invitation of the commissioners was not to discuss these points, but to ask their aid to carry out a scheme which they have consistently maintained would be injurious to their constituents, to the insured persons, and so to the community. Whether to decline such an invitation was an example of "rude ineptitude utterly without parallel in the history of this country" they leave to the public to decide, adding that some may think the description would more aptly apply to those who initiated the measure before consulting any representatives of the profession who would have to carry it on.

Dr. William Odling, after forty years' tenure of the professorship of chemistry at the University of Oxford, has sent in his resignation, to take effect at the end of next summer term.

Sir Ronald Ross has received a telegram from Surgeon-General Gannerman of the Indian Bacteriological Laboratory, stating that Captain W. S. Patton, I. M. S., of the King Institute of Preventive Medicine, Madras, has traced the complete development of the parasite of kala-azar in Indian and European bedbugs.

Simultaneously with an increased death rate there was a fall in the birth rate of the last quarter, ending December 31. This fall was more than in any fourth quarter since the establishment of registration. The natural increase of population in England and Wales by excess of births over deaths was last quarter 85,484. The previous year's fourth quarter figures were 90,061. In 1909 they were 92,147.

Sir William H. Allchin died on the 8th inst., aged 65. You will know the "Manual of Medicine," which he edited, and some of his many practical contributions to societies and journals. He was a popular dean of the Medical School of Westminster Hospital, to which he was attached for many years, passing through the several positions up to consulting physician. He was a senator of the University

of London, and served as an examiner to that as well as to the Conjoint Board of the Army and Navy Boards. He was one of the physicians-extraordinary to the King. He qualified in 1869; took M.B., 1871; M.D., 1892. He was elected F.R.C.P., 1878; censor, 1903, and in due succession Harveian, Bradshaw, and Lumleian lecturer. He received his knighthood in 1907.

The death is also reported of Dr. D. Mackinder, M.D. and F.R.C.S. Latin, at Hove, at the age of 93.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

MEDICOLEGAL QUESTIONS CONCERNING ALIENISTS—PSYCHIATRY AND THE PUBLIC—UNJUST ACCUSATIONS AGAINST DIRECTORS OF HOSPITALS FOR THE INSANE—COMMITMENT OF THE INSANE.

BERLIN, January 30, 1912.

A FEW weeks ago the medical profession in Berlin was greatly aroused over certain legal decisions on medical questions. The entire situation has been illumined in an excellent address presented before the Berlin Medical Society by Leppmann, and entitled "Questions of the day concerning alienists." He began by establishing the fact that of all the branches of medicine psychiatry stood alone not merely in not evoking the support of the laity, but even in exciting its antagonism. The result has been that recently inmates of asylums have been released, suits for damages have been brought by former inmates against directors of these institutions, and the most preposterous assertions have been spread broadcast in the daily press. The causes of the false notions entertained by the public as to the methods of the alienists lie principally in the fact that laymen regard insanity as incurable. They do not realize that there are periodical diseases of the mind in which the affected individual at times appears to the inexpert observer to be entirely normal. This is true not only of general paralysis, but also of degenerative diseases of the nervous system characterized by delusions. In these cases the condition of the patients before entering the asylum should be the criterion rather than their condition when surrounded by the favorable influences of asylum life. Failure to observe this rule accounts for the unjust accusation that directors of asylums harbor sane individuals in their institutions. Recently attacks have been made upon the methods of running private sanatoria for the insane. A striking instance of this occurred when an attorney suddenly appeared in one of these institutions and on the basis of a court order demanded the immediate release of an inmate. This peculiar state of affairs depended, on the one hand, on the imperfect statutes, and, on the other hand, on the narrow views of the court. Not long ago in the vicinity of Berlin the rights of directors of institutions for the insane were invaded with the sanction of the prevailing law. A barrister secured a court order giving him permanent access to an insane client. In matters of this kind a special law should be enacted giving directors of hospitals for the insane the right to exclude persons who may be detrimental to the welfare of the institution.

During the past few years suits for damages have been increasing. Those actions that have been brought against surgeons for unsuccessful operations have not been as unreasonable as those brought by insane individuals. In the former the physician is often in a position in which he is unable to vigorously defend himself. For example a woman claimed damages because her physician had directed the surgical nurse to perform a cerebral puncture, as the result of which marked syphilitic infection was demonstrated and contrary sexual feelings were aroused. Several lawyers dragged this case through a number of courts for an entire year, until their client obtained a verdict of $17,500. In addition to this loss the defendant had had years of worry, loss of time, and legal expenses. All of these might have been avoided if a preliminary examination had been ordered by the court as to the sanity of the plaintiff. The laws in Germany governing commitment of patients are not far-reaching enough and do not sufficiently protect the directors of hospitals for the insane. An instance of this is furnished by the following: An individual was committed by the court for having in moments of insane jealousy accused his wife of infidelity. The higher court, although it admitted the existence of insanity, ordered his release on the basis of the fact that the patient was able to follow his occupation as a master carpenter. Following his release, the latter brought suit for damages against his wife, the physicians, and the witnesses who had testified as to his mental condition. The trial, which will undoubtedly end with the rejection of the plaintiff's claims, will nevertheless prove a source of embarrassment to the physicians concerned. These instances cry aloud for a reform in the legal procedure of committing individuals to hospitals for the insane. In a case in which complete commitment is not feasible the court should at any rate have the power of partly restraining the business activity of the individual concerned. The speaker concluded his most illuminating address with the following recommendations: First, there is needed an insanity law which will regulate to the minutest details the commitment of the insane and the rights of the directors of asylums. Second, there are necessary revisions of the statutes relative to the restriction of the freedom of insane individuals in order that the latter may be protected from injuring themselves and prevented from injuring others.

The End Results of Surgery in Neurasthenics and on Neurasthenia. (With a Report of Forty-nine Cases.) E. Reynolds.
The Class Method in the Home Treatment of Tuberculosis and What It Has Accomplished. J. H. Pratt.
Primary Tumors of the Spleen. Report of a Case. G. McConnell.
Urinary Infection. B. Tenney and H. M. Chase.
The Prevention of Eclampsia. A. B. Emmons, 2d.
A Case of Chylous Ascites. Venous Peritoneal Anastomosis. Recovery. G. W. Morse.

End Results of Surgery in Neurasthenics and on Neurasthenia.—E. Reynolds summarizes as representing his own opinion a recent discussion on the subject of the end results of surgical work in neurasthenics. Neurasthenia is fundamental in the individual, i. e., typical neurasthenias appear only in individuals who are in one way or another ill developed or underdeveloped. Neurasthenia in itself is never an indication for surgical treatment, *i.e.* operations upon neurasthenics undertaken for conditions which would not warrant these operations in sound individuals are always injurious to the neurasthenic. Neurasthenia is not necessarily a contraindication to operation. Neurasthenics who are afflicted with remediable lesions which are causing symptoms sufficient to warrant operations in other individuals may expect the same benefit to their general health which would be expected in

sound individuals. In short, neurasthenics should not be denied the benefits of surgery. The author cites cases illustrative of a few of those causes of neurasthenia which are most common in gynecological practice. The first case illustrates the fact that the mere use of the generative organs may in some women precipitate a fatigue neurosis. The second case shows that imperfect generative development which is not important during maidenhood may be productive of symptoms after matrimony. The lesson taught by the third case is that a moderate autointoxication by the products of an inflammatory lesion may be the exciting cause of a neurasthenia.

Class Method in Treatment of Tuberculosis.—By J. H. Pratt. (See Medical Record, vol. 80, page 697.)

Primary Tumors of the Spleen.—G. McConnell notes the rarity of tumors of the spleen. The primary tumors of this organ are of necessity of the connective tissue type. From the trabecular cells there can develop the connective tissue tumors of the adult type, such as the fibroma, osteoma, lymphangioma, and hemangioma. The small round lymphoid cells may become greatly increased in number and give rise to considerable confusion, owing to the fact that in leucemia these cells are also increased. An endothelial proliferation may be present in many conditions, as in pseudoleucemia, Banti's disease, and primary splenomegaly. The author reports a case of endothelioma of the spleen in which there was a breaking down of splenic tissue due to the effect of a laceration aided by the erythrolytic action of the proliferating endothelial cells.

Urinary Infection.—B. Tenney and H. M. Chase state that bacteria of various sorts appear in the circulating blood and pass into the kidneys. These bacteria may filter through and leave no trace, they may damage the kidney in passing, or they may make a prolonged and destructive stay in the kidney. Meinhertz and others have shown that ligating the ureter on one side is followed by a venous hyperemia and a slowing of the venous current in that kidney. Meinhertz has found that tubercle bacilli in the blood during this condition are much more likely to settle on the affected side, in the capillaries and not in the tubules, and that they are found in connection with capillary thrombi. The authors' working theory based on these facts is that all causes producing obstructions to the flow of urine increase the chance of renal infection while they last and the rest of the process depends on the appearance of certain bacteria at the favorable moment. Their treatment based on this is the attempt to remove all causes of back pressure and to reduce the supply of bacteria in the circulating blood in all reasonable ways. When the infection is known to be tuberculous in only one kidney and the ureter is not greatly thickened, a few months of hygiene and the regular tuberculosis cure may be permissible for the patient whose financial means and disposition permit. A tuberculous kidney with a thickened ureter in the average patient seriously interferes with his comfort and his convenience, is almost certainly a progressive menace to health, leads to an extremely painful last illness, and needs nephrectomy like a malignant disease.

The Prevention of Eclampsia.—A. B. Emmons, 2d states that the prevention of eclampsia depends upon a system by which the earliest symptoms are recognized and the patient put in the care of an expert without delay. The types of women predisposed are those with constitutional nervous weakness; those under emotional strain, as unmarried girls; those with first pregnancies; those with chronic kidney disease, due often to a contagious disease in childhood, as scarlet fever; women accustomed to overeat and who are addicted to chronic constipation, and those who drink too little water. Eclampsia is more apt to occur in pregnancies developing great distention, as with twins or hydramnios. The suggestive signs and symptoms are headache; fear or dread, nervousness or anxiety; sometimes dullness or stupidity; disturbances of vision, as dimness, dizziness, spots or flashes before the eyes (albuminuric retinitis); scanty urination, with a large or small amount of albumen; swelling of the feet, hands or face; and high or increased blood pressure. A third class of symptoms may be distinguished: those which immediately precede, accompany or follow the convulsion, epigastric pain, complete anuria, jaundice, labor pains, total blindness, hallucinations, a somnolent condition, unconsciousness, and coma.

Chylous Ascites.—G. W. Morse reports a case of this condition in a man aged forty-two years. Repeated tapping was performed, but the fluid reaccumulated each time. Recovery finally occurred after anastomosis of the internal saphenous vein with the peritoneum. The etiology of this case could not be ascertained. The various causes to which chylous ascites has been attributed are chiefly the following: syphilis, filariasis, inflammation of the thoracic duct, pressure from a tumor, tuberculosis, thrombosis, rupture of the thoracic duct or transudation through its wall, and exotosis of the vertebræ.

New York Medical Journal.

February 24, 1912.

Relation of Intestinal Toxemia to Chronic Arthritis. C. C. Sutter emphasizes the fact that in some cases of chronic arthritis no definite cause can be discovered, while in others the removal of intestinal toxemia has been followed by cure or the symptoms have been relieved. On the other hand, he does not wish to create the impression that all cases of intestinal toxemia are accompanied by arthritis or that all such cases lead to organic disturbances. One must not overlook the fact also that intestinal toxemia often occurs secondary to arthritis. The toxemia which in one case may be the cause of arthritis, in another may manifest itself in arteriosclerosis; Bright's disease; cirrhosis of the liver; catarrhal otitis media; vascular and functional disturbances of the eye; skin lesions; functional disorders of the heart and vasomotor system; neurasthenia; obstinate headache; epileptoid attacks, etc. The following diseases are occasionally accompanied by arthritic manifestations: typhoid fever, bacillary dysentery, appendicitis, amebiasis, fecal retention, and various forms of ptosis of the abdominal viscera.

Creative Surgery.—R. Bellamy adopts this term as descriptive of the results obtained by him in restoring losses of continuity in tissues. He utilizes for this purpose grafts consisting of cells from the inner cellular membrane of the hen's egg, or strips of this membrane. These are applied to the wounded surface, after this has been rendered as nearly aseptic as possible. The grafts are preserved in a solution having the composition of sea-water, which solution is also used as a dressing for the grafted surface. From time to time new cells are introduced to facilitate the growth of structures or to hasten the growth of granulating surfaces. Sterile dressings are applied, but should not exclude atmospheric air, whose presence is necessary to hasten the growth of the tissues. The author reports a series of seventeen cases in which his method was successfully employed.

Sarcoma of Inferior Maxilla.—J. D. Whitall reports the case of a man aged twenty-three years, from whose

lower jaw the author removed successfully [illegible] and cervical sarcoma.

Combined Infestation with Ascaris and Hookworm.—E. Peelverta reports the case of a boy aged five years who, despite a combined infestation with ascarides and hookworms displayed remarkable powers of resistance following the receipt of an extensive lacerated wound of the arm and tetanic infection. The patient recovered.

Extradural Hemorrhage.—B. T. Tilton reports a case of emergency surgery, with inadequate instruments, performed in the Adirondack woods. The patient was a physician who had received a blow on the head, and shortly afterward presented evidences of extradural hemorrhage. The only instruments that the author could secure for making an opening in the skull were a small antiquated trephine with several teeth gone, a small gouge, and a carpenter's hammer. The trephine proved worthless, so the operator was compelled to chisel out the bone over the selected area. A collection of fluid blood estimated at about a small cupful was exposed and evacuated. There was discovered a wound in the posterior branch of the middle meningeal artery. As soon as the blood escaped, the brain began to pulsate normally and the congestion diminished. A small drain of plain gauze was inserted to prevent further hemorrhage and the wound was closed down to the drain. The patient made an uninterrupted recovery.

Fibrous Tuberculosis of the Peritoneum.—By C. L. Hall. (See MEDICAL RECORD, January 27, 1912, page 100.)

Anesthesia in Tonsil Enucleation.—G. Garthwaite-Fisher states that local anesthesia may be efficiently applied in the enucleation of the tonsil. Different solutions may be used to produce satisfactory anesthesia, but quinine and urea, alypin, and cocaine are the ones most frequently employed. The cocaine is to be used approximately in the strength of one-fifth of 1 per cent., that is, one grain of cocaine to seven drams of sterile water and one-half dram of adrenalin solution, one to 1,000. This latter prevents to some extent the absorption of the cocaine, and at the same time aids in securing a bloodless field.

Office Anesthesia.—A. E. Guedel has devised an apparatus by means of which a patient may administer to himself nitrous oxide and air for the purpose of producing brief general anesthesia, in minor operations performed in the physician's office.

Journal of the American Medical Association.

Tuberculosis of the Bones and Joints.—By H. J. Stiles. (See MEDICAL RECORD, Vol. 80, page 100.)

Treatment of Adult Joint Tuberculosis.—By L. W. Ely. (See MEDICAL RECORD, Vol. 80, page 100.)

Antityphoid Vaccination.—D. J. Davis reports the results he has obtained with this procedure in ninety-one individuals. The vaccine was prepared from four strains of typhoid bacilli recently isolated from the blood of typhoid patients and carefully identified by proper cultural and agglutination tests. The first dose contained five million dead bacilli and the second, given after ten or twelve days, contained a billion. The injections were all made on the arm over the lateral head of the triceps and the local reaction appeared in from two to four hours. The intensity varied. In some cases it was severe, the redness and swelling covering the arm from the elbow nearly to the shoulder, and in about half the individuals tenderness of the axillary glands was noticed. Occasionally slight tenderness and redness lasted over the usual period of two to four days. The general reaction began usually some hours later than the local one and was generally at its height in eight to twelve hours. It was generally most severe after the first dose. The symptoms were depression and headache, hot, dry skin, insomnia and restlessness, and a rise of temperature of not over a degree or two. No serious complications appeared in any case. A test for agglutinins was made in a number of individuals about two weeks after the last inoculation, and in all cases a positive Widal reaction was obtained. The author notes that a positive agglutination test in an individual who has had an antityphoid vaccination is of no value. According to Wright, the immunity after vaccination lasts about two years, but it probably lasts longer, and theoretically it should last throughout life. The author utters a caution in regard to the administration, pointing out that while no serious results have been observed, the typhoid vaccine has been given generally to young and healthy individuals and more severe reactions might be expected in less resistant persons. He also believes it advisable to modify the method so as to avoid the more severe reactions that sometimes occur, and a small dose at first—250,000,000 or less—would seem reasonable practice, increasing in the later doses. The administration would seem advisable for all persons having the care of typhoid cases. There should be, moreover, no let-up in the ordinary prophylactic measures against the disease.

Convalescent Carriers of Typhoid.—C. W. Gould and G. L. Qualls conclude from their investigations that a large percentage of typhoid convalescents leave the hospital as carriers. The gall-bladder is the harboring place of the bacilli which are excreted in the feces. The prostate is a factor to be considered in the male, as it excretes bacilli into the urine. People may expectorate typhoid bacilli. Hess's semisolid medium, as modified by Stokes and Hachtel, may be used to advantage for the examination of the urine and prostatic secretions. The solid color-reaction media are better adapted for stool examinations, because of the large variety of motile organisms contained in the stools. The leucocyte count of carriers is normal, averaging 8,000. The opsonic index and percentage of large mononuclear leucocytes were increased in the author's series of cases. The agglutination of typhoid bacilli by the serum of convalescents from typhoid or of the chronic carrier bore no relation to the carrier.

Streptococcus Vaccines in Scarlet Fever Prophylaxis.—W. H. Waters employed the method of Gabritschewsky in treating scarlatina as a streptococcus infection by means of the administration of broth cultures of streptococci previously killed by heat and phenol in doses of about 0.5 c.c. These doses are repeated in about a week. Cultures were made from a number of throats of scarlet fever patients and many strains of streptococci were isolated. These were combined in the manufacture of a polyvalent vaccine, standardized at 500,000,000 per cubic centimeter. The project was explained to hospital nurses, who were allowed to choose or reject the vaccine treatment as they pleased. In 1910 twenty-one non-immune nurses, who had never contracted the disease went on duty in the scarlet fever ward. Ten of these chose the treatment; eleven did not. In 1911 fifteen did similar duties. Of these, eleven received vaccines and three did not. One

received a single dose, but as she immediately contracted the disease within twenty-four hours her case is omitted. Her attack, however, was unusually mild, and it was the only one among the vaccinated nurses. Among the fourteen non-vaccinated nurses five contracted the disease.

Unequal Pupils as Early Sign in Tuberculosis.—J. L. Tuechter states that a pupillary difference as a symptom in unilateral pulmonary tuberculosis has been recognized for some time and is of some importance, deserving more attention that it has received. It is not always present, but if there is a difference it will be noted that the dilated pupil is sluggish, reacting slowly. A comparative dilatation of one pupil signifies an enlargement of the bronchial lymph-nodes on the corresponding side, and as such glandular involvement is usually tuberculous and occurs at a time when the lung itself does not show destructive changes, the author believes that the sign is most valuable in the early diagnosis of pulmonary phthisis. It is necessary to rule out ocular conditions which may cause the difference, and certain conditions of the thorax, such as tumor or aneurysm.

Paroxysmal Tachycardia.—H. M. Rich reports a case of this condition in which the heart rate was 220. The attack was controlled in the following manner: The author squeezed the chest-walls with some force attempting to exert pressure upon the upper part of the heart. It seemed that relief was obtained by direct pressure on the heart itself. If the pathology of the condition is, as Keith found, a fibrosis of the primitive cardiac streak, then the attacks are probably due to an occlusion of one or more blood vessels with a consequent derangement of the circulation in this important tissue. It seems to the author not improbable that a squeeze of the heart at this time might reopen the occluded vessel or vessels and re-establish the normal circulation with a consequent relief of the dependent phenomena.

Ovulation and Childbearing Without Menstruation.—O. T. Blankingship reports the cases of two sisters who had never menstruated, but had raised families of children. One woman had three children; the other had been married three times and had eight.

Cocaine in Ulcers.—G. L. Lydston states that in using cocaine as a preliminary to cauterization of chancroids he has come to the conclusion that the drug is useful in other ways than as an anesthetic. A tablet containing ¼ to ½ grain of the drug converts the ulcer within a few minutes into a vascular healthy surface from which exudes a bloody serum. The drug is rubbed into the ulcer lightly with a swab. The application is of great service in sluggish sores. It is a beautiful demonstration of the manner in which the drug favors hemorrhage in operations on the urethra, nose, etc. The rationale of the method is the same as that of the Bier method. Infection cannot long withstand the hyperemic assaults. The formula found specially serviceable for use by the patient is as follows: cocaine muriate, 20 grains; animal charcoal, 1 dram. Apply twice a day. Cleanse ulcer carefully with hydrogen peroxide and dry thoroughly before applying powder.

Cerebrospinal Meningitis.—E. Krulish believes that nasal sprays as ordinarily used for prophylaxis against cerebrospinal meningitis are unnecessary because of the obscure etiology of the disease. They do not destroy the germs. It is impossible to reach every portion of the nasal chamber and a normal nasopharynx is usually able to take care of itself. They are injurious from the facts that their use is likely to give the person a false sense of security and that the frequent use of the spray injures the delicate mucous membrane and lowers its vitality.

Research and Teaching in Medical Schools.—B. Ophuls sees a menace to medical progress in the foundation of special research institutes, especially when connected with educational institutions, unless they assume an educational function as well and do their share of teaching, and he is opposed to the establishment of chairs of research medicine. The mere existence of such a chair in a way reflects on the rest of the teaching faculty. Research work should be intimately associated with the clinics and the clinical teachers should be investigators. It does not follow that the only qualification a clinical professor needs is proficiency in laboratory work. There are comparatively few laboratory workers who possess all the experience and special talent required of a leading clinical teacher, but the latter should have a supplemental training in the methods of investigation.

Some Forms of Hemorrhage Difficult of Explanation.—W. Hale White states that in purpura the hemorrhage is not explained by deficient coagulation; this may explain why hemorrhage does not stop, but not why it began. It seems that toxins circulating in the blood and causing local damage to minute vessels probably explain why septicemia and some of the exanthemata are occasionally purpuric, although here it may possibly be that the microorganisms themselves cause the bleeding either directly or by the formation of infarcts. The menstrual flow is controlled by a hormone secreted by the ovary, for excision of both ovaries is followed by a cessation of heat or menstruation, and there is considerable evidence that the transplantation of an ovary from another subject into one who has ceased to menstruate as a consequence of the loss of both ovaries will restore heat or menstruation. The author directs attention to some facts which support the belief that pathological hemorrhage due to some substance circulating in the vessels and damaging the walls of the minute vessels may occur inside the body only. The subpleural ecchymoses that are frequently evident at autopsy in many instances indicate that some toxin has damaged the minute vessels. The hematemesis so commonly occurring in young women and associated with dyspepsia, pain, and vomiting is probably the result of an endothelial toxin causing hemorrhagic erosions. There are cases of renal epistaxis, or as it is more widely termed essential renal hematuria, without any evidence discoverable to the naked eye or microscope of a lesion in the kidney. The author suggests as the most feasible explanation of these cases that in them a poison—analogous to the menstrual hormone—is formed somewhere at intervals, and this reaching the kidney by the blood, and having a special affinity for the minute renal vessels so damages them that they rupture and the blood escapes. The same explanation is offered in connection with the attacks of epistaxis occurring at puberty in boys who are seemingly healthy.

Malignant Disease of the Testicle.—H. Morriston Davies states that all tumors of the testicles must be regarded as malignant. The history of previous venereal disease, the association of the swelling of the testicle with an injury, the length of the history dating perhaps from childhood, must not be allowed to outweigh clinical evidence. One should always suspect a tumor of the testicle when there is an oval swelling which is not translucent and comparatively painless. When the tumor is in

addition soft or elastic, and the surface shows slight lobulations the suspicions are confirmed. Increased pulsation of the cord is in favor of tumor, but is not pathognomonic. A solid tumor may be so elastic as to give the feel of a fluid swelling. The aberrant clinical manifestations of a testicular neoplasm must be constantly borne in mind. If the diagnosis is uncertain and the possibility of growth is entertained the tumor must be explored. Should the tumor be syphilitic, no harm will have been done; if tuberculous, or a hematoma, operation is the correct treatment. When the diagnosis of tumor is confirmed the complete radical operation, consisting of removal of testicle, cord, lymphatics, and surrounding fascia, and of the lymphatic glands in the region of the aorta and vena cava, must be done, unless the lumbar glands are extensively involved, or there are evidences of metastases elsewhere.

Tuberculous Mesenteric Glands.—E. M. Corner states that the results of his experience are that tuberculous mesenteric glands are found in practically every child submitted to an abdominal operation. The author believes that tuberculosis enters the body largely by way of the intestines, chiefly through the lymphatics of the ileocæcal region, and that, therefore, tuberculosis of the mesenteric glands originates there. Though there is a considerable risk of the generalization of tuberculosis from the infected mesenteric glands, in this situation the disease is not necessarily fatal. The children suffer from ill-health and abdominal pains referred to the umbilical region. These pains come on at night and sometimes after eating. The loss of appetite is often accompanied by some disturbance of the action of the bowels, more often inactivity and constipation than looseness of the bowels. The author has often done abdominal exploration on such children with chronic ill health, vague abdominal symptoms and discomfort, with or without a tumor on abdominal palpation. From a considerable experience with such cases he states that tuberculous mesentric glands and a somewhat dilated appendix containing fecal material, but otherwise not obviously diseased, are always found.

Removable Bladder Sutures.—C. Clarke has devised for closing wounds of the bladder sutures which he terms "tube sutures." These consist of the following parts: (1) Strands of ordinary strong silkworm gut; (2) short pieces of glass tubing, 2 inches long and ¼ inch in diameter, and (3) small brass or steel rings, ½ to 1 inch across. The sutures of silkworm gut are passed with a curved needle through the muscular coat of the bladder on both sides of the opening. Each suture is inserted not less than ¼ inch from the edge of the incision and emerges on the cut surface, just short of the mucous membrane of the bladder. The two free ends of the suture are threaded through a glass tube and drawn tight; they are then secured in this position by being firmly tied over the rim of one of the metal rings. The loop of silkworm gut which projects from the end of the tube and passes through the bladder wall acts like the loop of a wire polypus snare and holds the two sides of the bladder incision firmly in contact with each other. The other end of the silkworm-gut suture, knotted over the edge of a ring, is on a level with the surface of the abdomen and is easily accessible for the removal of the suture. To remove the suture the silkworm gut is divided close to the knot, and the knotted end is then pulled on until the suture is withdrawn. One hand at the same time holds the glass tube steadily in the wound. The silkworm gut remains quite taut after ligature in the tubes, and does not adhere to the bladder wall on removal. The tube sutures are easy to insert and to remove. No buried sutures are left in the bladder wall to form a focus for suppuration. The bladder can with safety be sewn up after cystotomy and the patient saved the discomfort of suprapubic drainage. In septic conditions of the bladder the glass suture tubes provide a ready channel of escape for any inflammatory exudates which may collect along the bladder incision. In cases where the bladder has to be reopened after operation, as, for example, to arrest hemorrhage, remove clots, or to provide drainage, the suture tubes afford a ready guide to the bladder incision.

Correlation of Symptoms and Signs in Some Abdominal Diseases.—B. G. A. Moynihan states that in more than one-half the cases in which an operation for gastric ulcer was deemed expedient by reason of the wearisome persistence of pain, vomiting and an occasional hematemesis, their stubbornness or open rebellion against the most assiduous and approved treatment, the stomach showed no evidence of textural change. A lesion could be found quite different from that expected—an adherent or obstructed appendix, a tuberculous ulceration of the ileum or the cecum, a prolapsed and perhaps obstructed stomach, or a calculous cholecystitis. The author states in spite of a diligent search which he has made during the past two years, he has been able to discover only very infrequently the "kink" in the ileum described by Lane. Whenever this is present he believes that it is secondary to appendicitis. The view he takes of "gastric ulcer" as described in the textbooks of to-day is that in the majority of cases it is not primarily or chiefly a lesion in the stomach, but consists of a persisting chronic infective lesion in, as a rule, some abdominal organ, and that in this focus more acute infections from time to time arise which cause those transient exacerbations in, or additions to, the symptoms which are sustained more quietly throughout the whole course of events. Whether the more quiescent symptoms are due to a secondary infective gastritis, to an enhanced or erratic activity in the secretions of the gastric juice, or to those irregular muscular conditions which are known as "pylorospasm," or to any combination of these, seems to be quite uncertain. According to the textbooks gallstones exist in the gall-bladder in 90 per cent. of the cases without giving use to any symptoms. The author takes issue with this statement. He states positively that gallstones never exist in any circumstances without the production of quite characteristic symptoms. Many of the so-called "functional" dyspepsias are associated with cholelithiasis. In patients who are undoubtedly suffering from cholelithiasis the occurrence of attacks of colic, rather milder in intensity than usual but of far greater frequency—say, four or six attacks in two weeks—especially if the attacks are associated with a mild form of chill, a "gooseflesh" sensation in the skin and a slight shiver, and if there is continuous loss of weight, the presence of a stone may with reasonable confidence be predicted.

Compressed Air Illness.—L. E. Hill states that it is not the exposure to increased atmospheric pressure that causes the condition known as caisson disease, but it is decompression that causes the trouble. There is no risk in going into or staying in a caisson; "*on ne paie quen sortant.*" The cause of the illness was suggested by Hoppe-Seyler and made clear by Paul Bert, whose experiments on animals showed that nitrogen is dissolved in the blood and in the tissue fluids in proportion to the pressure of the air. The dissolved gas on too rapid decompression bubbles off and effervesces in the blood of animal or man.

The bubbles, by blocking up the capillaries and cutting off the blood supply here and there, produce the symptoms. Exposure to high atmospheric pressure has no ill effect until the pressure becomes so great that the partial pressure or concentration of oxygen acts as a tissue poison. The illness which occurs on decompression is prevented by making the period of decompression sufficiently slow to allow time for the dissolved nitrogen to escape from the lungs.

Intrinsic Cancer of the Larynx.—St. C. Thomson notes that whereas extrinsic cancer of the larynx is usually a hopeless condition, it is quite otherwise with intrinsic cancer of this organ. He finds that by means of the operation of laryngo-fissure it is possible to obtain cure of the latter in 80 per cent. of the cases. He reports a series of ten cases, all of whom were males, whose ages varied between 43 and 68. The death rate from the operation was nil. As regards the diagnosis, huskiness more or less persistent, was the principal subjective symptom. In the majority of cases the diagnosis is made at once from the clinical appearances alone. The impaired mobility of the affected cord is, when present, a valuable symptom.

Esophageal Dilatation.—P. S. Hichens reports a case of this condition in an achondroplasic dwarf aged thirty-five years, who for three years before he presented himself for treatment suffered from pain and frequently from vomiting immediately after eating. An esophageal bougie was arrested 17 inches from the teeth, and on attempting to wash out the stomach with a stomach tube, the latter was arrested at the same distance from the teeth, and the fluid came back immediately quite clear and not all acid. The diagnosis seemed to be stricture of esophagus with subsequent dilatation. The diagnosis was confirmed by radiographic examination. The patient died, apparently from starvation, four years after he came under treatment.

Present State of Lung Surgery.—Fraenkel and Körte state that pneumotomy is an indication of necessity in certain forms of pulmonary abscess and in acute gangrene. The contraindications are based on widespread diffusion and asthenic states. In subacute bronchiectasis the conditions are somewhat similar, but there is not that need of haste in operating which obtains with abscess and gangrene, for in bronchiectasis there is always a possibility of spontaneous improvement. Compression therapy (artificial pneumothorax) is an amplification of lung surgery, which is especially adapted to phthisis which predominates on one side, and to circumscribed or unilateral fetid bronchitis. The indications for thoracoplastic operations are not yet definitely fixed owing in part to the natural severity of the intervention.

Methylism.—Hirschberg gives an historical sketch of our knowledge of this subject from the viewpoint of an ophthalmologist. As editor of the *Centralblatt für Augenheilkunde* he has consulted the files of the latter since its first appearance in 1877. In 1876 an episode occurred at Caen, in France, at the local prison which was not unlike the recent experience in Berlin. The men drank varnish made from wood alcohol. The symptoms comprised headache, gastralgia, vomiting, profuse sweating, coma, delirium, and in one case death. The pupils were widely dilated. One man who recovered readily from the intoxication was found to be blind as a result of acute double optic neuritis. Other men probably drank the poison in small quantities without apparent injury. During the next twenty years the subject is not once mentioned in the *Centralblatt*. About 1899, however, cases of blindness from adulterated spirits began to appear. In 1897 a wholesale poisoning occurred in Indian Territory, U. S. A. In one series of five individuals two died, two recovered completely, and one was blinded. Many episodes have since been reported from various parts of the United States, and among the offending substances which contained wood alcohol were Jamaica ginger, peppermint essence, bay rum, and cologne water. In 1899 the first case for Germany was reported by Kuhnt, and with this exception, not one case had ever occurred in that country until the recent Berlin episode. The victim worked in a methyl alcohol factory and had taken but one swallow of the product, but this was sufficient to blind him. In 1904 Buller and Wood collected notes of 122 deaths and 156 cases of blindness from acute methylism, practically all from English-speaking countries. In 1904 the first case to occur in Russia was reported, while five years later cases began to appear in Hungary.

Sokodu.—Under this name Frugoni of Florence describes the rat-bite disease of the Japanese. This a malady of protozoan origin and frequent occurrence in China and Japan; but that it is not an exotic disease is shown by its recent occurrence in Tuscany. The author has also found descriptions of it by Packard, the American surgeon, as far back as 1872, although its nature was not comprehended. Its occurrence has also been noted within the past two years in London. The author's case was in part as follows: Male peasant, aged 54, seen November, 1910, had been bitten by a rat two years earlier. After an incubation period of fifteen days' inflammation and ulceration set in at the scar and evidences of acute toxemia appeared. The proper lymph nodes became enlarged and a peculiar exanthem appeared. From that time periods of good health alternated with relapses without any actual periodicity. In the course of one such relapse, which was characterized by an eruption undistinguishable from erythema multiforme and by general prostration, there were noticeable ocular symptoms without any impairment of vision. These consisted of conjunctival injection, chemosis, and right-sided exophthalmos. The diagnosis was made from the history of rat bite and the known course and manifestation of the disease sokodu. The exophthalmos was due evidently to the formation of an acute edema in the retrobulbar connective tissue. The edema of the conjunctivæ was of the same nature, as were also the cutaneous efflorescences. It was necessary to exclude the presence of intestinal parasites, and this was done by establishing the absence of eosinophilia. Sokodu, then, is characterized chiefly by recurrent erythema multiforme.

Warfare Against Diphtheria.—Prof. Dietrich of the Institution for Contagious Diseases at Charlottenburg discusses the severe epidemic of this affliction which is visiting Berlin at the present time. So severe a visitation has not been experienced for decades. The preventive measures in force for some years past are thus seen to be unable to cope with the disease at its worst. This is due to the fact that in earlier years our knowledge of the modes of transmission was defective. At present we know that sources of immediate contagion may practically be disregarded. The part played by the permanent carrier of germs has long been known, but exact details have been wanting. It has been thought that any one might be a chance carrier, and that the bacillus might be present in the throats of any class of people as a mere saprophyte. At present evidence points to the fact that a carrier of the sort to be feared is almost necessarily some one who has been in close proximity to an actual patient for a considerable period, and who does not himself contract the disease. In future all who have thus been exposed in a family should be followed up. Naturally the actual patient becomes a carrier, too, but this fact has for many years been recognized and acted upon by quarantine. In children of school age the problem of the carrier is somewhat simplified by the custom of keeping sound children of the family out of

school for a definite interval. The preventive injections of antitoxin are only partially effective in sterilizing carriers. During the present epidemic the local authorities were much encouraged by the fact that it has not become necessary thus far to close any of the public schools.

Medical Aspects of the Italo-Turkish War.—Theilhaber spent last December in Tripoli. He found the heat excessive at noon, although in general it was tempered with winds. Resident physicians and apothecaries are not plentiful and entire areas are without any representation of this sort. The extreme poverty and fatalism of the natives make it imposible for such professions to be supported. As a German physician the author's aid was sought, but no one expected to pay anything. The most obvious affections were ophthalmias, malaria, and phlegmons. Hospitals and dispensaries are unknown and there is no conception of hygiene and sanitation. Under such favorable conditions for plagues it is not readily understood what compensatory factors exist which antagonize them. In the past centuries they have been common and severe enough. The common use of familiar utensils, cigarettes, etc., and the universal custom of kissing even among grown men do not seem to spread disease among the troops. There was a military lazaret which contained only wounded men who as a class had received no first aid, nor, in fact, any suitable care. As a rule vital organs were not affected. The Turks were naturally much advanced in modern culture when compared with the Tripolitans. They have a Red Crescent Society based on the various Red Cross organizations, and the few physicians in its employ, together with some volunteers, were gradually introducing civilized methods among the natives. They were hampered in all respects—by want of supplies, poor transportation facilities, official red tape, etc. The French and German Red Cross Societies who were endeavoring to operate among the Tripolitans were also hampered in various ways. The former sought to use Tunis as a base of action. The Italians apparently refused to allow any of these foreigners to pass through their lines.

Münchener medizinische Wochenschrift.

January 30 and February 6 and 13, 1912.

Bloodless Treatment of Piles.—Boas, starting with the fact that prolapsed hemorrhoids may readily be reduced if done at once after prolapse has occurred, has developed a technique, based on mechanical principles only, for combating the affection. The cases adapted for his treatment are characterized by the ready reducibility of the hemorrhoidal mass. The application of Bier's cups to the anus also leads to a diagnostic criterion, for if hemorrhoidal nodes appear under the influence of suction the case is eligible for the treatment, although it by no means follows that the latter will prove curative. The cups are now used regularly in the expectation that the stasis and edema which result will lead to the obliteration of piles by thrombosis. The method in detail is as follows: The patient is put to bed for a period of five days, at the close of which he may or may not be moved to a reclining chair. As a rule, the actual period for treatment is from eight to fourteen days, at the close of which the occupation may be resumed. The cups are applied from half an hour to an hour, or, in general, until edema is produced. The more intense the edema and the longer it persists, the better the prognosis. The author evidently expects to cure his cases in a single session, for he does not mention consecutive sittings during the brief period of treatment. The constriction produced by the edema has all the force of a ligature. In four years' experience the author has never seen gangrene or any other serious complication. He has cured thirty patients during this period, and commends his method as by far the best of the bloodless procedures.

Classical Symptoms of Cerebral Plexiform Angioma.—Isenschmid speaks of the rarity of this condition, which makes diagnosis difficult. He analyzes a case in a child of nine which appeared to date from a mild skull injury six years earlier. The first symptoms appeared when the child was four years old in the form of attacks of headache, vomiting, and vertigo. Choked disks appeared later as evidence of a periodically increased intracranial pressure. Two attacks were attended with unconsciousness and Jacksonian epilepsy, followed by transitory hemiparesis. In a subsequent attack consciousness was retained and there was no convulsion, only slight hemiparesis. A loud systolic murmur was heard over the skull, most pronounced over the right ear. The arteries leading to the brain were dilated, especially on the right side, and there was a mass of dilated veins at the outer border of the right orbit. The diagnosis was greatly facilitated by a radiogram, which revealed the circulatory anomalies. The patient improved after ligation of the right common carotid. A second case occurred in an adult, likewise dependent originally on a series of cranial injuries of unknown severity (patient was a mason's apprentice in youth and was often hit by falling objects). At the age of twenty-four he began to suffer from headaches and attacks of unconsciousness at long intervals. At thirty-two he had developed a spastic hemiparesis of fluctuating intensity and, generally speaking, the course and symptoms of the case were much like those of the preceding. The nature of the lesion was suspected, along with possible intracranial aneurysm. Upon the patient's decease from pneumonia an autopsy could not be obtained. It was deduced that the angioma occupied the right temporal region.

Industrial, Universal Argyrosis.—Koelsch excludes from consideration not only local industrial argyrosis, but the general and local types due to the medicinal use of silver preparations. The type of the industrial form is disseminate local, not universal. The latter form has been known since 1896, when Schubert described the cases of some Bohemian artisans who used certain silver solutions for coating glass pearls. A little of the solution was taken into the mouth, so that to all intent the argyrosis which resulted was of the same genesis as the medicamentous variety. The author, however, has recently studied quite a different type, in which the silver must have reached the tissues either through inhalation of dust or penetration through the skin, or both. The subjects, both women, were workers in silver leaf, and their task was to cut the leaves and lay them in the books. One subject, aged 27, had worked at her occupation steadily for fourteen years. The discoloration of the skin was first noted when she was 18, and it increased steadily for the next four years, since which period there has been no further change of any sort. The discoloration affects chiefly the exposed parts and visible mucosæ, evidently because sunlight exerts a distinct reducing action. It is, however, evident to some extent on the covered integument. The other patient was 50 years old, had begun to follow the occupation at the age of 14, and first noticed the discoloration at the age of 21. Both women were delicate in appearance and both were blonds. Each one exhibited anemia and disordered digestion several years before the appearance of the argyrosis. Such cases are naturally hopeless, for while the condition is in theory amenable to chemotherapy, the substances which would have to be administered are all highly toxic. Blonds and anemic women should not work with silver, and if they cannot choose, the silver line on the gums should be watched for as a safety signal.

Destructive Action of Radium Emanation on the Integument.—Mesernitzky describes an illustrative

ase. A worker with radium was experimenting with a small glass tube containing emanation to the amount of 130 mg. It was necessary for him at times to hold the tube in both hands, one end between two fingers and the thumb. After two weeks he noticed reddening of the ends of both thumbs, and shortly afterward of the ends of the index and middle fingers. In the course of a few days these red areas became thickened, livid, and slightly necrotic. Pus formed and desquamation also resulted. For the entire evolution, beginning with the first exposure, five weeks were required. The author has seen similar cases, but never before one in which pus formed. The subject was a particularly healthy one, so that general predisposition could be excluded. The case is not to be confounded for a moment with lesions which might result from exposure to large doses of radium and tends to show that emanation is not necessarily an indifferent gas.

Bromine-Urea Derivatives as Hypnotics.—Glombitza discusses several of these synthetics which have been introduced into practice under various proprietary names. Since veronal has obtained widespread recognition attempts have been made to secure preparations of the same therapeutic efficacy which will not lend themselves to suicidal attempts and injurious self-dosing. Veronal contains a double ethyl group, to which its efficacy is doubtless largely due and the synthetic chemists have sought to introduce this group into a molecule containing bromine and urea. Some of the products have been on the market for a long time. Thus far the most that can be said pro and con is that they do not seem to be toxic or cumulative in proper doses and do not tend to addiction; that the possibility of intoxication in large doses and combination with other hypnotics is by no means excluded; that the therapeutic action is uncertain; and that owing to the relatively large doses demanded the cost is excessive.

Vaccination and Rabbit Control.—Poundorf gives a full account of the methods by which the vaccine manufacturers at a government institute make use of rabbits to assist in standardizing and otherwise controlling their product. The animals are vaccinated from a stock vaccine. Should the latter be no longer virulent, the result is negative or atypical. In successful vaccination the temperature begins to rise during the third day; at this period it is possible to vaccinate other rabbits. During the next twenty-four hours the rabbit is killed and the vaccinia area excised *en masse* and nailed to a board. The virulent material is then scraped off with a curette. The dead animal is now examined very carefully for the possible presence of tuberculosis or other disease. In nine years' experience at the institute it has never been necessary to reject vaccine because of disease in the animals. This vaccine may be used for human vaccination, and the reaction is somewhat milder than when bovine virus is used. After rabbit vaccine has taken it is impossible to vaccinate successfully with bovine virus. Rabbits may be inoculated successfully with variola pus from human subjects. Pus obtained from the rabbit was inoculated into a calf, pus from the latter into another rabbit, while from another calf inoculated from the latter a child was successfully vaccinated. The vaccinia was typical save for a number of accessory vesicles developed inside the affected area. Vaccinated rabbits are able to communicate vaccinia to others in ordinary common intercourse. In this way primary lesions have occurred in the eyes with destructive consequences, and epidemics of vaccinia may occur among the rabbit colonies. The chief sources of exposure are friction and crawling into the same burrow.

Typhoid Carrier in an Educational Institution.—Bernhuber describes the following episode: Two boys in a boarding school were taken at the same time with typhoid, as was also an officer of the institution. Three others of the pupils or teaching body were also attacked in the same manner, but their cases were not under observation at the same time and place. Nine years earlier and five years after the first establishment of the school the first case of typhoid had occurred, a pupil having been the victim. There was no other case during the ensuing five years. At the end of this period there was a petty epidemic which comprised two kitchen maids and a pupil; one year later another kitchen maid was attacked and went home for treatment. A sister took the disease there and died. At the same time a pupil was attacked and went to his home, returning to school after his recovery. In the next year a preparatory student who was fed from the school kitchen, but did not live in the building, chanced to die of erysipelas. A servant girl of his household then developed typhoid and before the expiration of the year two more pupils were attacked by the latter. Other cases developed later, making sixteen within four years. Naturally the water supply, drains, etc., had been accused and much money spent on sanitation, all to no purpose. The existence of a carrier was now suspected, and the feces of the kitchen personnel were investigated. The head cook, a woman of seventy, was found to be a carrier. Her stools contained a pure culture of Eberth's bacillus. Two girls who had been through the fever were found to be sterile in this respect. The cook had had typhoid twenty-two years earlier. She had been at the school since its foundation and had been in the family of the school head for thirty years, as had a younger sister, who presented a few bacilli in her stools for a short time only.

Erysipelas Treated with Antidiphtheritic Serum.—O. Polák reports good results from this method of treatment. The average stay of the patients in the hospital was reduced from twenty-five to thirteen days. Twenty-four to thirty-six hours after the injection of the serum the temperature fell to normal, provided there were no complications.—*Casopis Lékarú Ceskych.*

Traumatic Rupture of the Aorta.—S. D'Antona states that there are many varieties of rupture of the aorta corresponding to the mechanism of its production, the conditions of elasticity and resistance of the vessel walls, and the blood pressure at the time of injury. The author reports three cases, all of which resulted from serious accidents and ended fatally. He then attempts to unravel the mechanism of the production of these accidents, basing his examination on physical and physiological data, on the nature of accident, and the seat and conformation of the lesion. In direct wounds such as gunshot wounds, there are two methods of production depending on an abnormal increase of blood pressure, and an excessive tension on the vessel walls. The majority of lesions are due to an increase of vascular pressure. Traction has little effect on the aorta on account of the latter's position against the spinal column. Violent extension of the spinal column does little harm. The arch and beginning of the descending portion of the aorta are the parts generally injured. Increased blood pressure is felt by the aorta on account of the normally high pressure in it, the quantity of blood that it contains, and the velocity with which it flows. The sudden arrest of the body in a fall produces a suddenly increased blood pressure in the aorta. The author believes that the projection of the ventricular wave is one of the marked elements in the injury sustained. The portion of the aorta corresponding to the cicatrix of Botalli is most subject to traumatic rupture. The intima and media are injured independently of each other and in an opposite direction. The intima yields to the dilating force because its fibers are longitudinal, while the circular fibers of the media are firmer.—*Archivio per le Scienze Mediche.*

Insurance Medicine.

STATISTICS OF DIABETES IN FRANCE.

At a recent meeting of the Académie des Sciences Dr. Le Goff read an interesting paper dealing with the increase in diabetes as a cause of death as registered in the French statistics. In 1880 there were 128 deaths in the city of Paris registered as due to diabetes, which gave an average of .044 per 10,000 inhabitants. In 1885, that is, five years later, the number of cases had increased 100 per cent., the deaths numbering 261 and giving an average of 1.105 per 10,000 of the population. In 1890 the deaths numbered 304, showing an average of 1.345 per 10,000. In 1895 there were 370 fatal cases; in 1900, 427 people died from diabetes; in 1905, 443. The latest statistics given were those of 1909, during which year 525 deaths occurred, or a death rate of 1.930 per 10,000 inhabitants.

From these figures it is seen that in thirty years the number of deaths from diabetes has quadrupled, which is in reality an enormous increase, and some reason for this must exist. Le Goff gave as reasons for the great increase: (1) Diabetes occurs more among the well-to-do classes who eat and drink large quantities and who take little or no exercise. (2) The great increase in the quantity of sugar which is consumed nowadays, for it has been noticed that in the countries in which the greatest amount of sugar is consumed the statistics of diabetes are higher than in the other countries. In 1910 the consumption of sugar per head in England was 40.710 kilos; in America, 31.100 kilos; in Switzerland, 26.77 kilos; Scandanavia, 18.97; Holland, 17.68; France, 15.700; Belgium, 12.64. From these figures it is noted that the consumption of sugar in France is much below that in England, but we may suggest that a possible factor in the production of diabetes may be the wine drinking which exists in France in contradistinction to the spirit drinking in England. It is well known that the effects of wine are a potent factor in the production of liver disease, with a resulting derangement of the sugar metabolism, and this may account in one way for the great increase in mortality from diabetes in France.

Insurance of Persons Residing in or Removing to a Tropical Climate.—Braun says that he could not find any classified data which could be utilized in judging the increased risk taken in insuring persons residing in the tropics. It seemed evident that an increased premium should be required, yet there were no facts for estimating the amount of increase reasonably called for. He has therefore taken the trouble to gather much available information in regard to this problem.

While mortality among Europeans who have taken up residence elsewhere is different from the mortality in Europe, it differs but little in case the new places of residence are in the temperate zone. Thus mortality in New South Wales, in South Africa, in the temperate regions of South America as well as in Canada and the United States of America, is much the same as in Europe. Japan shows somewhat higher mortality among children and youth, but about the same figures among adults.

In subtropical and tropical lands, on the other hand, the figures are much less favorable. In India the mortality is twice, and for certain ages three times as high as European figures. In the German colonies of tropical Africa the mortality, likewise, is from one and one-half to three times the mortality in European Germany. Infectious diseases and diseases of the gastrointestinal tract show an especially high mortality in tropical regions.

Three classes of applicants must be differentiated: those who have returned from the tropics to the temperate climate; those who reside in the tropics; those who expect to travel or to take up residence in the tropics.

The first group of applicants must, of course, be judged by the results of medical examination, which ought to show whether any damage has resulted from life in the tropics; the second group is of interest only to such insurance corporations as have established or intend establishing business branches in the tropics; the third class presents the most actual interest at the present time.

If an applicant declares that he has no intention of removing to another climate, and later does so, the insurance companies have usually continued their policies at the usual rates, as the number of such unexpected removals is too small to make it worth while to classify them into a separate group. Certain insurance companies, however, issue limiting clauses in their policies in regard to indemnity in case of traveling or removing to another climate; most of the American and English companies are very liberal in this respect and their policies may be termed "world" policies. If an applicant declares that his intention is to travel in tropical climates or to reside there, every element must be considered in deciding the character of the policy to be issued. His health must be judged in relation to the dangers he is exposed to in the special climate of his new residence. In the future, conditions of the policy to be issued must be worked out after a study of the mortality in the tropics, but at present this is not possible. Braun has therefore collected available information about the special risks of the tropical climates.

The characteristics of a tropical climate consist of intense sunlight, the height of the average air temperature, the absence of great differences between seasonal temperatures as well as between those of the day and night, and the usual stability of the barometer. Humidity is likewise a very important factor, and its degree is frequently of such a height as to make almost unendurable a fairly high temperature. The absence of large variations in the daily temperatures diminishes loss of heat from the human body by simple radiation, and thus puts extra work on internal organs. The activity of the heart and of the lungs is usually increased. Disturbances of the digestive and of the nervous systems are frequent consequences.

Sunstroke, heat prostration, nervous irritability and prostration may, of course, be prevented by proper food, clothing, and shelter. The infectious diseases of the tropics, on the other hand, are much harder to escape. Malaria, blackwater fever, and yellow fever belong to such diseases. Modern sanitary measures, exemplified by the events in Havana and in Panama under American control, have diminished very much the dangers of these diseases, but still the mortality from them much exceeds that in the temperate zone.

Certain special points must be considered in judging a "tropical" risk. The occupation of the applicant is of greater importance than in the usual risks because it may decide whether the patient is to be more or less exposed to the dangers of tropical life. If the applicant is married and is accompanied to the tropics by his wife, the danger seems to be less according to some statistics. Age is of little consequence. Acclimatization is an important factor and all details about previous life in the tropics, if there have been any, must be carefully considered. The health of the individual is of more importance in the tropical risks, and all applicants with weakness of the circulatory or the nervous systems should not be taken as risks.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, January 1, 1912.

Book Reviews.

Nervous and Mental Diseases. By Archibald Church, M.D., Professor of Nervous and Mental Diseases and Medical Jurisprudence in Northwestern University Medical School, Chicago; and Frederick Peterson, M.D., Professor of Psychiatry, Columbia University. Seventh edition, revised. Octavo volume of 932 pages, with 338 illustrations. Price, cloth, $5.00 net; half morocco, $6.50 net. Philadelphia and London: W. B. Saunders Company, 1911.

The seventh edition of this standard text-book on nervous and mental diseases does not differ very greatly from its immediate predecessor either in size or in the method of treatment of the subjects. In the part on Nervous Diseases a description of amyotonia congenita has been added, and some of the sections, notably those on pellagra, poliomyelitis, and cerebrospinal meningitis, have been quite extensively revised. The chapters in the psychopatic section have been rearranged and in part rewritten to make it accord with the prevailing system of classification of mental diseases. Not that the author recommends the classification, for he thinks that any attempt at classification in the present state of our knowledge of the pathology of insanity is futile. The difficulty of the subject is made plain by the fact that no less than forty classifications of insanity have been made, most of which would long since have been lost had not their authors taken the precaution of having them put into print. Dr. Peterson enumerates six of the latest and best of these and then gives the statistical and clinicopathological classification adopted by the New York Commission in Lunacy for use in the State Hospitals. After treating of the toxic and infection-exhaustion psychoses in the general etiological section, he divides his chapters into manic-depressive insanity, dementia præcox, senile dementia, general paresis, paranoia, neuropsychoses and idiocy, imbecility, and feeble-mindedness. This is a good working classification and perhaps the best for practical use that can be made in the present state of knowledge of the subject.

Blood-Vessel Surgery and Its Applications. By Charles Claude Guthrie, M.D., Ph.D., Professor of Physiology and Pharmacology, University of Pittsburgh; Former Professor of Physiology and Pharmacology, Washington University; Instructor in Physiology, University of Chicago; Demonstrator of Physiology, Western Reserve University, etc. Illustrated. London: Edward Arnold. New York: Longmans, Green & Co., 1912.

This book is the third of a series of monographs by first-hand authorities on medical and surgical subjects of immediate interest, the series to be known as the International Medical Monographs. As the general editors justly say in their preface, amidst the press and rush of modern research, and the multitude of papers published in many tongues, it is necessary to find men of proved merit and ripe experience, who will winnow the wheat from the chaff, and give us the present knowledge of their own subjects in a duly balanced, concise, and accurate form.

This is a very laudable aim, and if the editors can only live up to it they will undoubtedly have done a great service for the medical profession. And if they choose as authors such authorities on their particular subjects as is Professor Guthrie on blood-vessel surgery they assuredly deserve to succeed. The work of Guthrie is too well known in this country to require detailed reference. Together with Carrel he has assisted in revolutionizing this form of surgery, and in the words of the general editors they have brought within the realms of possibility, under favorable conditions of locality, the removal of an aneurysm and the restoration of vascular continuity by the insertion of a sterilized graft taken from the post-mortem room.

The chapter dealing with the transplantation of tissues is in part an exposition of the most marvelous results obtained by Guthrie, that of the successful grafting of hen's ovaries without vascular anastomosis. It would seem as the outcome of these experiments that the evidence is in favor of soma, or foster-mother, influence in the after-breeding of hens thus treated, as all the controls have bred true. These experiments cannot fail to be of great interest to those concerned with the problems of heredity.

The last chapter of the book, too, is in a high degree instructive. In this Guthrie discusses resuscitation and shock. He attributes traumatic or physical shock to a general inhibitory state and of course his suggestions for treatment are in line with this theory. Blood-vessel surgery is a very excellent résumé of the most recent knowledge on the subject written by the man who has done the most and best original work therein. The book itself is well printed and the illustrations are numerous and, what is more to the point, are satisfactorily clear and serve the purpose for which they are intended, namely, to elucidate fittingly the text. If all the books of the series are up to the standard of this last then there can be little doubt of their success from the scientific and material standpoints.

Die experimentelle Bakteriologie und die Infektionskrankheiten mit Besonderer Berücksichtigung der Immunitätslehre. Ein Lehrbuch für Studiernde, Ärzte, und Medizinalbeamte von Dr. W. Kolle, o.ö., Professor der Hygiene und Bakteriologie an der Universität und Direktor des Institutes zur Erforschung der Infektionskrankheiten in Bern; und Dr. H. Hetsch, Stabarzt in der Medizinalabteilung des Kriegsministeriums in Berlin. Dritte, erweiterte Auflage. Zwei Bände. Berlin und Wien: Urban und Schwarzenberg. Price $8.50 and postage. New York: Rebman Company, 1911.

It is gratifying to note that the popularity of this work is sufficient to justify the publishers in the issuance of a third edition within three years of the appearance of the second. This permits the authors to keep their book in line with the really extraordinary progress which is making in bacteriology. Of course, many important changes have been made. The chapters on immunity, anaphylaxis, spirochetal infections, trypanosomes, and syphilis have been almost entirely rewritten, and the evidence of extensive revision is apparent through the rest of the book. Epidemic poliomyelitis, Weil's disease, trachoma, and verruca peruana have been added to the list of infectious diseases, and space is devoted to serodiagnosis and chemotherapy. It is sufficient to say that the third edition maintains the high standard set by the previous ones. The illustrations deserve special comment. They are numerous, and well executed, and many are beautifully colored.

Grundlinien einer Gesunden Lebensweise. (Briefe an einen gebildeten Laien.) By Dr. med. Paul Sittler, Colmar i. Els. Price 1.30 mark. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

This little volume of 74 pages contains many helpful hints for those interested in the subject of hygienic living. Among the topics treated are the feeding of infants and children, dangers of artificial feeding, suitable diet for adults, dangers of excessive use of meat, water as food, clothing, and hygiene of dwellings.

Die experimentelle Pharmakologie als Grundlage der Arzneibehandlung. Ein Lehrbuch fur Studierende und Ärzte von Dr. Hans H. Meyer, Wien, und Dr. R. Gottlieb, Heidelberg, Professoren der Pharmakologie. Zweite, neubearbeitete Auflage. Berlin und Wien. Urban und Schwarzenberg. Price $3.50 and postage. New York: Rebman Company.

In the revision of this well-known work for its second edition the authors have rewritten the chapters on the pharmacology of the genital organs and the pharmocological influence of the cause of disease. The plan of the book in taking up the action of drugs by physiological systems offers a distinct advantage not found in the study of a drug in its entire action. The section on "etiotropic" drugs, that is, those directed against the cause of disease, has naturally increased greatly in importance, and it is gratifying to find it so thoroughly adequate to the demands that will be made upon it. This able exposition of chemistry, physiology, and pharmacology forms a sure foundation for true scientific therapeutics and will be appreciated as such.

Health for Young and Old. Its Principles and Practice. By A. T. Schofield, M.D., M.R.C.S., etc. Author of "Hygiene for Schools," "Fit for Work," etc. An Unconventional Manual. Price $1.50. New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1911.

This volume, which the author calls unconventional, does not contain the ordinary statistics or diet tables found in many works on hygiene. The object of the book is to outline general hygienic rules appropriate for individuals of various ages. The effort is made to discourage introspection and the attitude of anxiety in regard to one's individual health. Various subjects are discussed in a helpful and pleasing way. The text is arranged in chapters which are considered under two sections: The Principles of Hygiene and the Practice of Hygiene. A variety of subjects is offered to the reader, for the writer tells us what to breathe, what to wear, what to eat, what to do, and how to wash. He also considers health in its relation to age and sex, town and country life, and how to restore health. The book is completed by a good index.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 15, 1912.

DR. GLENTWORTH R. BUTLER, VICE-PRESIDENT, IN THE CHAIR.

Presentation of Portrait of John A. Wyeth, M.D., LL.D.—Dr. SIMON BARUCH said that he had the honor of presenting this portrait, painted by J. Campbell Phillips, in behalf of the many friends of Dr. John Allan Wyeth. They desired to add it to the gallery of presidents now gracing the hall. With due regard to that innate modesty which was a dominant characteristic of their friend he would refrain from reciting the many valuable services which Dr. Wyeth had rendered to the medical profession and to his specialty, surgery. Nor was it necessary, for they were all aware that Dr. Wyeth had been the recipient of every honor in the gift of his colleagues. He had been president of the county and State medical societies, of the Academy of Medicine, and of the American Medical Association. Dr. Baruch asked the indulgence of his hearers while he read a few of the numerous letters that he had received indicating the character of the men who had participated in this movement and which revealed the motives which had prompted the admirers of Dr. Wyeth to do him honor. The first was from the "grand old man" who never failed to respond to any call in the interest of his profession, Dr. A. Jacobi. The second letter was from one of Dr. Wyeth's predecessors in the chair, Dr. Joseph D. Bryant. The third letter was from a man known for his scientific contributions, Dr. I. Adler, who wrote that Dr. Wyeth had done a great deal of good in his profession and had made the New York Polyclinic what it was going to be, a really first-class institution. The fourth was from one of those brothers who had converted a small city in the West into a surgical mecca and whose institution and work were the marvel of the world's surgeons, Dr. W. J. Mayo, who wrote: "My dear Dr. Baruch, I notice in the JOURNAL that you are the chairman of a committee to obtain a portrait of my old friend and teacher, Dr. John A. Wyeth. I enclose a contribution. I would send more, but I presume your object is to give as many men as possible the opportunity to join in this testimonial to the greatly beloved master of surgery." Dr. Baruch said that there was nothing that he could say that would add weight to these encomiums and added: "Mr. President, the portrait of Dr. John A. Wyeth is now the property of the New York Academy of Medicine."

Experiences with Duodenal Alimentation.—Dr. MAX EINHORN presented this paper. (See page 450.)

Duodenal Alimentation.—Dr. WILLIAM GERRY MORGAN of Washington, D. C., read this paper in which he related his experience with duodenal feeding. For the benefit of those not acquainted with the duodenal tube he outlined the technique of its use. The tube was swallowed by the patient at bedtime with the aid of water. When the first mark on the tube was at the teeth the bucket on the end was entering the stomach. The second mark indicated the distance from the mouth to the pylorus. During the night the capsule, provided there was no obstruction, would usually have passed the pylorus and the third mark should then be at the teeth indicating that the end of the tube was *in situ*, well down in the duodenum. One could make sure that the tube was in the duodenum in several ways. Gentle traction would develop a slight resistance if the tube was in the duodenum. Aspiration through the tube would often recover golden yellow duodenal juice and not gastric secretion. If the patient was given some liquid to drink by mouth and aspiration was immediately performed it would not be returned through the tube as would be the case if the latter were coiled up in the stomach. The food that had been found most satisfactory was a mixture of milk, sugar of milk, and raw egg. The amount given at a feeding should be small at first, 100 c.c. every hour from 7 A.M. to 9 P.M., increased until 280 or 300 c.c. were taken at each feeding. When the patient was taking 280 c.c. of milk, one egg, and one tablespoonful of sugar of milk at each feeding he was getting approximately 2,840 calories for the total eight feedings in twenty-four hours. As the average individual required when in bed under 2,000 calories to maintain his nitrogenous equilibrium it could be seen that there was a liberal amount in excess of needs for the purpose of building the patient up. In treating his first patients Dr. Morgan thought it would be an advantage to employ a method like that of Murphy for giving salt solution per rectum and he had made use of gravity from a pint irrigating jar, connecting its tube with the duodenal tube by a glass connection and setting the rubber petcock so that the nourishment entered the duodenum slowly, about twenty-five minutes being required for the larger feedings. Duodenal feeding was not, as a rule, suitable in the home as there were a number of points to which it was necessary to adhere rigidly or untoward happenings would occur. The food should be administered at the body temperature as that normally entering the duodenum from the stomach was of this temperature and the duodenum was not accustomed to shocks of too high or too low temperature and resented such insults by distressing symptoms of shock. The food should be allowed to enter the duodenum slowly; too rapid administration would cause flatulency and often the same train of symptoms as variations of temperature. The food mixture should be heated slowly, but should not be made too hot lest it become thick and lumpy from cooking of the egg. After heating it should be strained; this would help in preventing the tube from becoming occluded. At the termination of each feeding a syringeful of water at the body temperature should be injected; then the petcock closed; the syringe filled with air; the petcock again opened and the air injected, after which the petcock should again be closed before the syringe was disconnected. This kept the tube clear and clean. The management of the petcock was not a trivial matter; if it was not turned off when the syringe was removed some of the food would likely rush back into the bucket and lower tube and be converted by the trypsin into a cheesy lump, defying removal until the tube was removed. Duodenal feeding was indicated in certain ulcers with severe symptoms which would hitherto have been treated at the beginning by rectal feeding for some time, but which did well when put on duodenal feeding at once. If an ulcer had not yielded to a thorough course of medical treatment duodenal feeding should be tried before resorting to surgery. While this method of treatment would not cure all cases of ulcer and some might have to be operated upon later, the general condition of the patient was decidedly improved so that he was a better surgical risk. Ulcers at the pylorus, producing obstruction, might be treated with duodenal alimentation provided the duodenal tube could be passed into the gut, but if the pylorospasm persisted they then demanded gastroenterostomy. Duodenal alimentation should not be given too long a trial in ulcer at the pylorus because of the danger of malignancy. In other ulcers this method of treatment should be instituted in nearly all cases after ordinary medical means had failed to produce a cure and would often bring about very happy results. He had never had a case in which no improvement whatever was noted. Many complete cures had resulted and the remainder were greatly benefited. The cases that were not of long duration had almost without exception done well. Dr. Einhorn had recommended the local application of healing agents by painting argyrol in nearly insoluble form on the tube at the point where it rested against the ulcer. The writer

had not had a large experience with this method, but he had administered various drugs through the tube for other conditions arising during the course of duodenal feeding. In the diarrheas which often accompanied duodenal ulcer prompt relief was often secured by one grain of argyrol in an ounce of warm starch water given through the tube. Flatulence caused by the milk not agreeing perfectly could often be controlled by the addition of thirty drops of glycerine to the feeding. If flatulence still persisted five drops of ichthyol in a little water through the tube was generally followed by good results. Where the stool showed deficiency of bile the administration of one or two minims of dilute hydrochloric acid in one ounce of water through the duodenal tube caused the yellow bile color to reappear promptly. The author had also secured excellent results in the treatment of duodenal catarrh by using a long duodenal tube. Results had been most striking in cases of visceroptosis of marked degree with ischochymia where it seemed as though the stomach was incapable of emptying itself and passing along sufficient of the forced feeding to increase weight and restore the general tone. The stomach was given a rest and at the same time food could be introduced into the body in sufficient quantities to cause increase in weight and improvement in muscle tone. One of the cases cited nicely illustrated this point. The author felt convinced that duodenal feeding constituted a mark of great progress in medicine, filling a long-felt want; it was a method of resting the stomach and at the same time affording the economy abundant nourishment.

Dr. Henry Dwight Chapin said that he was called upon to speak from the standpoint of the condition of the pylorus and stomach in these cases. Dr. Einhorn had spoken of the stomach as being a reservoir; if that was true in adult life, it was particularly true in early life. It seemed to be a sort of receiving chamber through which the food could percolate into the bowels and there be digested. The musculature of the stomach and bowels in infants was weak, and this explained the failure, in so many cases, of attempts in forcing the contents of the stomach through the pylorus. In addition, in early life there were very thin muscular fibers and there was a tendency to spasm, a pylorospasm, such as was seen in the muscular fibers of the sphincter of the anus where many infants had a simple spasm, who were very constipated, and the fecal mass was not allowed to pass through. This same thing was noticed in cases of intussusception where the bowels was so distended. This was also found in the bronchial tubes where there was a weakened musculature. Dr. Chapin said that two years ago he had made a study in a series of cases, all weak infants, of the musculature of the stomach walls and of how long the food remained in the stomach, and in only two cases did he find the stomach emptied in the time it should have been. There were eighteen failures to empty the stomach in the allotted time. The fermentation test was present in thirteen of these cases, probably because of the food remaining in the stomach too long. In nineteen of the cases at the end of three hours only six approximately emptied the stomach of its curds and whey in this time. Butyric acid was present in six of them. Hydrochloric acid in six, combined hydrochloric acid was found in a fairly large amount. With this weak musculature of the stomach, with a pyloric spasm, there was a serious condition to deal with. This condition of pylorospasm was a condition that Dr. Chapin believed to be more frequent than was generally supposed. The question was, what should they do regarding it? Hitherto they had washed out the stomach every two hours, etc. He had had a number of cases in which a relief of the spasm at the pylorus was obtained by the use of paregoric, given a few drops at a time, about one hour before feeding. This seemed to relax the spasm. However, he had recently been using the tube devised by Dr. Hess, one that was somewhat larger than the one used by Dr. Einhorn, and which could be passed through the pylorus. There was a suction produced and the contents were received into a receiving chamber which showed just what they were dealing with. He had fed cases slowly, taking from ten to fifteen minutes. He had one case at present with all the typical symptoms of spasm of the pylorus, constant vomiting, loss of weight, constipation, and with a beautiful wave from the pylorus.

Dr. C. J. MacGuire said that in 1910 he had a number of cases of hemorrhage from gastric and duodenal ulcers and the results of the treatment then employed were not at all satisfactory. He always labored under the disadvantage then of having to support his patients by means of rectal alimentation. He then read a brochure by Dr. Einhorn and what was contained therein appealed to him. Until he had seen the demonstration just made he did not realize how simple this method of feeding was. He reported the case of a patient, twenty-six years of age, who had had three severe hemorrhages within five or six days and the girl was in an exsanguinated condition. She was treated for this condition for four days and without relief and was then taken to Dr. Einhorn, who introduced his duodenal tube. During the first two days the girl's weight decreased and she lost during this time about two pounds, but then she began to gain in weight. She suffered no discomfort. The tube was retained for thirteen or fourteen days and was then removed. Her weight during this period of time increased from 117 to 122 pounds. The patient left the hospital in December and was absolutely cured and had since been in good health. Another case Dr. MacGuire saw was one of a similar character, but more desperate. For four days the patient had been supported by rectal alimentation. The tube was introduced and allowed to remain for twenty-four days and, as a result, the patient's weight increased, and even after the removal of the tube the weight continued to increase. This patient was now enjoying life and showed no symptoms of gastric distress whatever. In duodenal alimentation they aimed to give the stomach a rest and to support the patient. There should always be considered the general health of these patients, and especially in those cases where operation had been refused; in these cases duodenal alimentation would prove of great benefit. Dr. MacGuire said that both of these cases occurred in his service at St. Vincent's Hospital; in both the usual treatment for gastric and duodenal ulcer hemorrhage was carried out for four days when duodenal alimentation was started. In the second case the weight increased from 110 pounds (March 4) to 130 pounds (May 4). The red blood count in the last case fell to 1,800,000. When the patient left the hospital this count had reached 4,100,000. His contention was that an ulcer was most likely to heal in a subject who was fairly well developed and nourished by duodenal feeding than in one merely fed by rectal alimentation.

SECTION ON SURGERY.

Stated Meeting, Held April 7, 1911

DR. HENRY DAWSON FURNISS IN THE CHAIR.

Unilateral Renal Hematuria: Decapsulation.—Dr. Henry Dawson Furniss reported the case of a man forty-one years old. When eighteen years of age he had typhoid fever. In July, 1900, he was thrown from a wagon and received an injury of the lumbar region; there was no hematuria and recovery was prompt. This history was taken on January 3, 1911. Three weeks before the patient noticed that the urine contained blood which varied in amounts. At times it was port-wine in color, at other times coffee-colored. There always seemed

to be more in the morning specimen. The radiographs of the kidneys, ureters, and bladder were negative. The cystoscopic examination showed the bladder to be normal. The urine from the right kidney was bloody, that from the left was clear. The examination of the eyes was negative. The blood pressure was 125 mm. On January 13 the kidney was explored through a lumbar incision and appeared to be normal. A decapsulation was done and a small wedge-shaped piece of the kidney from the convex border was removed for examination. For three days after the operation the urine contained as much blood as before operation. On the fourth it began to clear up, on the fifth day none was found macroscopically; on January 23 the urine was normal. The patient left the hospital on January 26. Dr. H. T. Brooks examined the tissue removed and reported that it showed very little deviation from the normal. The most marked change consisted of occasional small wedge-shaped areas of fibrosis, with the base toward the capsule, and confined to the cortex. The capsule, except at these points, was not thickened nor infiltrated with round cells. A few tubules in the cortical portion were filled with a coagulated, transparent, homogeneous (hyaline) material resembling sections of casts; others were filled with blood. Blood was also observed within the capsular spaces of several of the Malpighian bodies, and the capillaries of some of the glomeruli belonging thereto were widely dilated with blood. Except for an occasional tubule filled with hyaline coagulated material the medulla presented nothing abnormal. The larger vessels showed no degenerative changes. How much of these alterations, except the slight fibrosis mentioned, was produced by the removal of the tissue was, of course, impossible to state. On April 6 the patient stated that, except for an attack of appendicitis shortly after reaching home, he had been in good health since leaving the hospital, and that within the past four weeks he had gained nineteen pounds in weight. He had had no return of the hematuria. The specimen of urine presented was perfectly clear.

Chronic Suppurative Pyelitis (Ascending).—Dr. Furniss reported the case of a woman sixty-five years old. In December, 1907, she had had a pan-hysterectomy performed for carcinoma of the uterus. Shortly after there developed a ureterovaginal fistula on the left side which Dr. Furniss repaired by a plastic operation through the vagina in August, 1908. She was relieved and was well until two months ago, when she began to be troubled with irritability of the bladder. The urine was quite turbid and there was a heavy sediment. Cystoscopy revealed a normal bladder mucosa, with clear urine coming from the right kidney. The left ureter appeared as a round opening, the diameter of a match stick; from this purulent urine was seen escaping. On March 25, 1911, the left kidney was removed. The kidney was smaller than normal and was quite adherent; the pelvis and the calices were much distended; the kidney structure was thinned out from the pressure atrophy. In the two weeks since the operation the patient had improved very much. There was very little irritability of the bladder and the urine was clear.

Epidural Hemorrhage, Complicating Epilepsy.—Dr. Walter C. Cramp presented a patient who had been subject to epilepsy for seventeen years. One day before admission to Bellevue Hospital, during an attack, he fell and then walked two flights of stairs to his room where, twenty-four hours later, he was found unconscious with paralysis of the left arm and leg. There was edema over the right parietal region. His pulse was 60 and respirations were loud. The blood-pressure was 120. The patient was very restless but could be aroused from his stuporous state by shaking. Operation revealed an epidural clot over the right motor area; there was also a fracture of the skull in this area extending into the base. There was a rupture of the posterior branch of the middle meningeal artery. On the day following the patient could move the left arm and leg; two days after operation he could speak intelligently, give his correct address, and could move the extremities freely. When discharged he had normal use of his left arm and leg.

Penetrating Stab Wound of the Abdomen Involving Mesentery and Intestine.—Dr. Walter C. Cramp presented this patient. The knife entered two inches below the umbilicus, slightly to the right of the median line. When admitted to the hospital six inches of omentum protruded from the wound; this was washed off with saline solution and excised. The peritoneal cavity was filled with blood. A wound one and a half inches long was found at the base of the mesentery which was the site of the profuse hemorrhage. Three wounds in the jejunum involved all the coats; there was also a wound in the transverse colon. The patient was discharged after a stay of eighteen days in the hospital.

Infection with Bacillus Aerogenes Capsulatus.—Dr. Cramp reported this case. The patient fell through an elevator shaft, receiving a compound fracture of the os calcis and astragulus. After twenty-four hours gas escaped from the wound and the tissue became emphysematous. The patient was treated by an open incision, peroxide of hydrogen, and exposure of the wound to the air. Twenty-four hours after there was no gas escaping from the wound. The culture taken showed the presence of the *Bacillus acrogenes capsulatus* and streptococci. It became necessary to amputate the leg and then the thigh. This was performed under spinal anesthesia.

Multiple Lacerations of the Intestines.—Dr. Henry G. Bugbee reported this case, which showed the extensive injuries which might be obtained by a penetrating wound of the abdomen. A splinter from a piece of wood penetrated the patient's abdomen, and within an hour he was placed on the operating table. There were two lacerations of the transverse colon, and lacerations of the jejunum as well, one-half to two inches in length. The operation was rapidly performed. No large vessels, fortunately, were injured, and the patient made an uneventful recovery.

Gunshot Wound of the Head.—Dr. William Henry Luckett presented a man, twenty-one years old, a lumberman, who received a gunshot wound of the left temporal region. At the time of admission he had considerable difficulty in speech, evidently understanding, but unable to articulate clearly. There was no astereognosis. His chief complaint was pain in the head. There was no paralysis. The *x*-ray showed the bullet in two pieces as though split longitudinally. One piece was apparently just outside the skull, the other just beneath it. Both pieces were easily removed, and the patient made an uneventful recovery.

Butcher's Cleaver Wound of the Brain.—Dr. Luckett presented a patient who had been struck on the head with a butcher's cleaver. He bled profusely, but did not lose consciousness. There was no bleeding from the nose. On admission to the hospital his temperature was 97° F., pulse 88, respiration 20. The local injury consisted of a lacerated wound of the scalp slightly to the left of the sagittal suture at the vertex of the skull, and was about three inches in length. A portion of the left parietal bone was lifted away as a lid; it was movable, and there was a linear fracture three-quarters of an inch from the sagittal suture. The temperature never went above 100° F. Two days after admission the patient was examined by Dr. Leszynsky, who found the sensorium to be clear, pupils equal, and reaction normal. The corneal reflexes were normal. There was no rigidity of the neck or extremities. The facial innervation and the tongue were normal. All the movements were normal except that there

was inability to extend completely and abduct the fingers. There was no astereognosis. There were no objective sensory disturbances. The deep reflexes were equal and exaggerated in all four extremities. The plantar reflexes were normal. Four days after admission some clots and lacerated brain tissue were removed; the bone was replaced and the scalp wound was closed by suture and dressings applied. After the operation the temperature rose to 102° F., pulse 100, and respirations to 22. On the fifth day after the operation conditions appeared to be normal, although the patient seemed stuporous and ecchymosis appeared under the left eye. There were a paralysis of the right arm and exaggerated right knee jerks. There was also motor aphasia. One day after the operation the patient was again examined by Dr. Leszynsky. There was an ecchymosis of the left upper and lower lid, and the eye was closed. The motor aphasia still persisted. There were a right facial paralysis and a complete flaccid paralysis of the right upper extremity. The right knee-jerk was slightly exaggerated. There was neither clonic rigidity nor Babinski's sign. The corneal reflexes of the right side were abolished. The condition presented was probably one due to subdural hemorrhage over the middle and lower third of the precentral convolution. Eleven days after admission a left subtemporal decompression was performed, with trephine and rongeur; there was found a large clot beneath the dura at this point. This was evacuated. Eight days later the patient was able to speak for the first time since operation. His arm was still paralyzed, but apparently there was some improvement. The paralysis at one time was so complete that the head of the humerus began to slide from the glenoid cavity. The use of massage and passive motion helped the patient to concentrate his mind on his efforts at active motion. The patient continued to improve daily. When he was discharged from the hospital the wound in the skull was practically closed, although the dura was plainly visible and the pulsations of the brain were easily seen.

Stab Wound of Head.—Dr. LUCKETT presented a patient who was stabbed in the head by a penknife about six weeks prior to operation. The wound was dressed at another hospital, where the knife blade escaped notice. The wound healed, but broke down several times and discharged pus. On admission to the hospital he complained of pain in the head; he also had chills and fever, convulsive attacks and dizziness, and was indisposed. On January 10 the patient had a convulsive seizure lasting ten minutes, with temporary loss of speech and paralysis of the left arm. On January 11 he was examined by Dr. Leszynsky, who found the patient conscious and able to answer questions intelligently. There was no disturbance of speech. The tongue was normal. There was a slight facial paresis. There was no rigidity of the neck. The pupils showed equal reaction. The left upper extremity was generally paretic, but the patient was able, with some difficulty, to completely elevate and extend the extremity. There was complete wrist-drop, with loss of grasping power from paralysis of the flexor group of muscles. He could supinate, but not pronate, the forearm. The triceps muscle was paretic. The elbow and wrist-jerks were normal. There was no astereognosis. The lower extremities were normal. On January 11 an *x*-ray was taken, and this showed a foreign body embedded in the brain in the right parietal region. Dr. Luckett trephined over the spot and removed a button of bone with the blade intact. The blade was about one and one-quarter inches in length. On the day following the operation the patient had several convulsions. On January 27 there was a complete flaccid paralysis of the entire left upper extremity. The left wrist and elbow-jerks were exaggerated. There were *complete astereognosis* and incomplete loss of muscular sense. There were no objective sensory disturbances. The knee-jerk was slightly increased. There was no clonus; Babinski's sign was not present. The diagnosis in this case was an injury to the subcortical portion of the motor tract affecting particularly the arm center, with indications of probably descending degeneration. The patient was discharged on February 24 with fair power in the flexors and extensors of the arm, but the wrist-drop remained and the flexors of the hand were very weak.

Fracture of the Base—Decompression.—Dr. LUCKETT reported the case of a man, forty-two years old, who had been struck by a trolley car. When he was admitted to the hospital he was bleeding profusely from the right ear. His pulse was strong and respirations were normal. There was a lacerated wound of the scalp two inches in length, over the right frontal region, and one about the same length over the right occipital region. Depression was felt through the occipital wound. There was a facial palsy on the right side. The first night in the hospital he was very noisy and irritable. The facial palsy was probably due to a fracture of the petrous portion of the temporal bone or to a hemorrhage into the Fallopian canal. A lumbar puncture revealed a large amount of blood. An *x*-ray showed a fracture extending through the right temporal bone extending into the base. After eight days with no improvement in his condition it was decided that an operation was demanded. Ten days after the injury a right subdural decompression operation was performed and a large extradural clot was found. The dura was incised and about two ounces of clear fluid escaped. Twelve days after the operation the right facial palsy had entirely disappeared. There was a gradual return of muscular and mental power, and the patient was discharged cured less than one month after admission.

Extensive Fracture of the Base Without Symptoms.—Dr. LUCKETT reported the case of a boy, twelve years old, who was hit by a car. When admitted he had a depression of the skull in the occipital region; there were also contusions of the face and skull. There was false motion and crepitus at about the middle of the left femur. When first seen he had motion in the right upper and lower extremities. In the ambulance he developed clonic convulsions and became unconscious, but regained consciousness shortly after admission. In the right occipital region there was felt a bony ridge with a slightly movable fragment. A spinal tapping showed pure blood. The physical examination showed the left femur with a point of false motion, crepitus, and very severe pain in the upper third. There was some swelling, but no ecchymosis. There were no signs of external violence.

Severed Flexor Tendons at Wrist—Tenorrhaphy After Interval of Four Weeks.—Dr. WINFIELD SCOTT SCHLEY reported the case of a boy who had his tendons at the wrist severed. He was immediately taken to a doctor in the neighborhood who ligated the radial artery and sutured the wound without reuniting the severed tendons. Four weeks later Dr. Schley opened the wound and did a tenorrhaphy with perfect results. The tendons appeared to have had new sheaths formed for them.

Mesenteric Thrombus—Resection of Twenty-two Inches of Intestine.—Dr. SCHLEY reported this case. The patient was taken ill twenty-four hours before admission to the hospital with sharp pains especially in the lower abdomen. Two hours after the beginning of his attack he vomited. No blood was passed and the bowels moved normally. No gas was passed. There were neither rectal nor urinary symptoms. He had a temperature of 100.3° F., respiration 24. His leucocyte count was 20,000. The abdomen was moderately distended, with some rigidity. He was thought to have some abdominal lesion and an exploration was made. Upon opening the abdomen about 100 c.c. of bloody serum escaped; the mesentery was found to be chocolate colored, and its veins thrombosed. It was

necessary to remove 22 inches of intestines which were filled with a brown, bloody detritus. The third day after the resection the colon was irrigated. The patient still had within him the button; otherwise he was apparently normal in every way.

Tuberculous Peritonitis.—Dr. SCHLEY presented a man with the most advanced tuberculous peritonitis complicating pulmonary tuberculosis he had ever seen. There was an exceedingly extensive involvement. He did a laparotomy which was followed by a slight improvement in the patient's condition. The abdomen was again opened and the cheesy masses were less prominent. A third operation was performed and then the temperature subsided and his general condition improved decidedly. The patient was kept in the open air and sunlight, creosote was administered, and at the present time the patient was almost entirely free from his active tuberculosis.

Pancreatic Cyst—Acute Development—Study of Ferments.—Drs. CHARLES H. PECK and W. G. LYLE reported the case of a woman, twenty-nine years old, who was admitted to Roosevelt Hospital on October 26, 1910, complaining of pain and tenderness in the upper abdomen, accompanied by fever and general malaise. Since her sixteenth year she had suffered with flatulency and epigastric distress after eating. After two miscarriages she gave birth to three children; the last two were living and in good health. Fifteen months ago, during pregnancy, she had three attacks of severe lancinating pain which radiated to the shoulder and downward to the lumbar region. This continued about twelve hours. Two of these attacks were accompanied by syncope. Since the birth of her child she had had, within eleven months, four similar attacks; she always vomited shortly after the pain began; this was usually one or two hours after meals, and the pain lasted from twelve to twenty-four hours. The patient had had neither typhoid nor jaundice. She did not pass bloody or clay-colored stools, and never noticed blood in the vomitus. On admission her temperature was 101.2° F. and pulse 84. The leucocyte count was 18,000 and the polymorphonuclears were 79 per cent. The Widal test was negative, and the gastric contents were practically normal. On examination a tender mass, thought to be an enlarged liver, was found in the upper right quadrant of the abdomen, extending across the epigastrium. After several days' observation, during which the pain and tenderness continued and the temperature ranged from 101° to 102° F., an operation was performed on November 1. The liver was found to be normal. The gall-bladder contained six good-sized facetted stones and about thirty small ones. Its wall was practically normal. There was no dilatation of the ducts, and no stones were found in them. The head of the pancreas was greatly enlarged, hard, and nodular. No areas of softening or necrosis were found. The diagnosis of cholelithiasis with a marked pancreatitis was made and a cholecystotomy was performed. The drainage tube was kept *in situ* twelve days; bile continued to escape from the tract several days longer. The pain, abdominal tenderness, fever, nausea, and prostration continued, and it soon became evident that the epigastric swelling was increasing. Twenty-two days after the cholecystotomy the second operation was performed. The swelling in the epigastric region proved to be a collection of fluid which lifted the stomach and transverse colon forward. It was incised through the gastrocolic omentum and about 1,500 c.c. of watery fluid were evacuated. While it occupied in general the position of the lesser omental cavity it seemed certain that there was not a collection of fluid in that cavity, but rather that the anterior wall of the sac was formed by the *posterior* parietal peritoneum which had been lifted forward, for large masses of necrotic pancreatic tissue lay in the bottom of the cavity, several of them attached by fibrous bands, evidently the remains of the pancreatic vessels or ducts. The amount of viable pancreatic tissue which was left could not be determined, nor could the exact position of the area of necrosis, though they were apparently in the region of the head. Drainage was free and pieces of necrotic tissue escaped with the fluid. The convalescence was slow, but uninterrupted, and the patient left the hospital on December 28. She had since reported having gained in both weight and strength. The formation of the cyst was evidently the direct sequel of the pancreatitis observed during the first operation. Localized necrosis of a considerable mass of pancreatic tissue had occurred, and with this extravasation of fluid and the rapid collection of the large amount found. The anterior cyst wall was formed by the posterior parietal peritoneum. The posterior wall was formed by the posterior parietes and the pancreas. The formation of this cyst in the way described would seem to suggest that many pancreatic cysts might have a similar origin, beginning with a pancreatitis, localized necrosis, and the pouring out of pancreatic secretion. As the cases seldom came under observation until the process was more chronic, the direct proof of this origin was seldom at hand. The examination of the fluid from the cyst was made by Dr. Lyle in the Research Laboratory. It contained a very active ferment which proved to be erepsin, a proteolytic enzyme which readily digested peptones and albumoses, but differed from trypsin in that it did not digest native or coagulated albumins, with the exception of casein. The ferment in another case under observation at the same time, in which the cyst had been present for about one year, was trypsin.

An Unusual Case of Strangulated Femoral Hernia with Comments Thereon.—Dr. G. FRANKLIN SHIELS reported the case of a woman, fifty-four years of age, the mother of four children, who had been operated upon nine years since for repair of the perineum and cervix. The patient was extremely rheumatic and had cardiac insufficiency. She was taken suddenly while walking with slight pain in the groin, followed by violent colicky pain in the epigastric region. Three hours later she became aware of swelling in the groin. She continued to have some pain in the back and epigastrium associated with a sense of bearing down. Dr. Shiels saw the patient thirty-two hours after the beginning of her trouble, and found a swelling the size of a tangerine orange over the inner third of Poupart's ligament, which was firm and resilient to the touch, and which lay below and to the outer side of the spine of the pubic bone. A diagnosis of strangulated femoral hernia was made, based upon the suddenness of occurrence, the colicky pain, and the nausea. Attempts at reduction failed. Dr. Shiels stated that in his opinion no effort at taxis lasting longer than five minutes should be made in any case of hernia with symptoms of obstruction or strangulation, and that operation should be done at once. The sac was easily freed from the surrounding tissue at operation; this had been bruised by the early efforts at reduction made by the attending physician. It was filled with a non-odorous, flake-free, dark, serosanguineous fluid. At the deepest part of the sac was found a portion of the bowel not larger than an oxheart cherry, firmly strangulated by the ligament of Hey, purple-black in color, but glistening. The bowel was freed and returned to the peritoneal cavity. The sac was thoroughly freed high up, ligated, and removed. An uninterrupted recovery followed. Dr. Shiels said that he reported this case because of its extremely sudden occurrence, without special strain, and the remarkable absence of urgent and violent symptoms. He wished to point out the failure of many writers and teachers to call sufficient attention to the anatomical mechanism which caused the hernia to find its way to a point over Poupart's ligament, thus leading to its being mistaken for an inguinal hernia and to futile and misdirected efforts at reduction, *i.e.* taxis upward, outward, and inward, instead of downward, to bring the hernia

ver the external femoral opening, backward to place it in the canal, upward and inward to return it within the abdominal cavity. The experienced surgeon should remember the relationship of the hernia to the pubic spine and should at once make a differential diagnosis, for the femoral hernia was, in contradistinction to that of the inguinal type, always below it and to its outer side. He also reported the case because he had predicted so accurately the condition which existed before operation, because he had seen a case some years ago so exactly like this one in every detail and at operation only a portion, and not the whole circumference, of the bowel was strangulated, having been pushed laterally into the canal and nipped by Hey's ligament. The extreme rarity and sudden occurrence of femoral hernia he thought was due to the so-called femoral canal *not* being a canal except potentially, and *not* having any contents, while the inguinal canal *was* at all times a canal, and thus was a weaker point of attack in those having a hernial tendency. He directed attention to the fact that after removing the sac high up nothing was done in the way of closing or obliterating the femoral canal, since nothing further was needed to bring about the radical cure of femoral hernia. The various procedures resorted to for the purpose of producing a barrier to the descent of the hernia were quite unnecessary. Dr. Ochsner of Chicago had been emphasizing this point, which it had been the custom of the writer to practise and to teach since 1895. When the sac was removed high up the walls of the potential canal fell together and through the irritation produced by the operation an exudation of plastic lymph occurred which, becoming organized, obliterated the canal. Finally, he observed that the early epigastric pain had ceased to be regarded by surgeons as indicative of stomach or duodenal trouble alone, since operation had repeatedly proved that it might be a symptom of involvement of any organ covered by or coming in contact with the peritoneum. This was no doubt due to the coming together of the extensive sympathetic system of the abdominal organs in the solar and splanchnic regions.

Hemorrhagic Infarcts of the Small Intestine.—Dr. Howard D. Collins read this paper and reported three cases. He said that circulatory disturbances of the blood supply of the small intestine that presented themselves to the surgeon were usually of such a character as to ultimately produce a gangrene of the gut. In addition to injury to mesenteric vessels by trauma, constriction of the vessels by volvuli, intussusception, strangulated hernia, etc., which might be called obstruction by external causes, there were those of internal causation, such as emboli and thrombosis of the mesenteric vessels. Moist gangrene was the only type observed provided the artery alone or the vein alone was occluded. That anemic gangrene did not occur when the artery alone was stopped was easily explained by the fact that the mesenteric veins had no valves, and consequently the affected part was bathed in venous blood by a return engorgement from connecting veins. Dr. Collins reviewed the experiments of Longcope on dogs which led to the conclusion that extreme narrowing of the mouths of the superior mesenteric artery or celiac axes, or both, in dogs was soon compensated for by a collateral circulation, so that a gradual thrombosis of one or both vessels might take place without serious detriment to the health of the animal. Longcope also concluded that sudden occlusions of the superior mesenteric artery resulted in hemorrhagic infarcts of the intestine. If the analogy between dogs and humans held true there must be cases where a slow-forming occlusion of the superior mesenteric artery occurred with gradual, but more or less complete, cessation of the blood supply by the normal channels to the small intestine, and yet gangrene be averted by collateral or anastomatic vessels. Such cases probably pass unrecognized, while in those cases where the occlusion was sudden the symptoms were so severe as to cause anxiety, and usually led to operation. The principal symptoms were sudden pain of a marked degree, abdominal rigidity and tenderness, fever, either marked constipation or stools mixed with blood. Hiccough was often present, as well as a leucocytosis of high count. Another symptom was a doughy sensation in that part of the abdomen overlying the turgid swollen gut; this doughy area moved about as the position of the gut was changed. Later on the gangrene produced a septic peritonitis. The prognosis depended upon the amount of gut to be resected and the condition of the patient. There was a type of disturbance of splanchnic circulation which presented as its pathological lesion single or multiple small hemorrhages in the wall of the gut, usually the ileum, without any thrombosis or embolus of the superior mesenteric artery or vein while lying between the mesenteric layers of the peritoneum. The hemorrhagic spots usually lay between the muscularis and serosa or in the submucosa, and were placed opposite the mesentery. These areas varied from one to three centimeters in diameter. The writer had called this condition "intestinal apoplexy." Dr. Collins described three cases which Maragliano had reported, all of which had septic peritonitis when he first saw them. All of these cases died, and autopsy showed not only the perforated ulcers of the lower part of the ileum, but in addition several areas of hemorrhage like those just described. Sprengel had also described a case that gave the signs of intestinal obstruction, which on operation showed some bloody serum and numerous intramural hemorrhages scattered through the small intestine. Two of Dr. Collins' cases had been mild, only a single spot of hemorrhage having been found, while the third had multiple areas. All were subjected to operation and all recovered. Two other cases had occurred in the City Hospital, both in the service of Dr. Potter. One was supposed to have typhoid, and died suddenly. Autopsy showed many minute hemorrhages in the wall of the small intestine, none having perforated. In reviewing these cases it might be argued that the symptoms in the first two cases were out of all proportion to the lesions found, but on the other hand the cessation of symptoms after the operation was very remarkable. It might also have been questioned whether these patients would not have recovered without operation, the hemorrhagic spots resolving without perforation. He was of the impression that perforation would surely have occurred and resection furnished the most reliable means of forestalling that accident. The writer had nothing to offer as to the etiology of these cases.

PRACTITIONERS' SOCIETY OF NEW YORK.

243d Meeting, Held December 1, 1911.

The President, Dr. J. W. Brannan, in the Chair

Preliminary Note on Some Experiments on Serous Gas Distention.—Dr. A. A. Smith read this paper. (See page 462.)

Dr. Smith supplemented his paper by remarking that the first experiments on the cadaver were directed to demonstrate that the pericardium would distend with liquids. The experiments showed that there is a limit to such a distention; such a limit being of 750 c.c., although a maximum of 1200 c.c. could sometimes be reached. Several *x*-ray photographs demonstrated that the pericardium was distended at the base of the heart, and that the heart was displaced toward the chest walls to the left side. One of the photographs demonstrated the leakage in the pleura from the distended pericardium on perforation of pleura by the point of the needle. The experiments were concluded by introducing the liquid in the pericardium by penetrating through the right auricle, passing through the jugular vein,

the innominate, the superior vena cava and the right heart, and by perforating the heart muscle, thus leaving the pericardium intact. The result of the experiments on the dogs (under ether, of course, and with due precautions for the animals) did not interfere with Dr. Dunham's theory. It resulted that the pericardium distended uniformly, and that when the liquid reached a given pressure it greatly interfered with the function of the heart, while, when the pressure was relieved the heart resumed its natural function; this for several times.

The experiments for the distention of the pleura in the cadaver were not as successful, particularly on account of the difficulty of penetrating the pleura with the liquid. Dr. Smith showed one of the *x*-ray photographs to demonstrate the displacement of the heart toward the right side to the fifth intercostal space, and in commenting upon it, expressed his doubts whether such a result could be obtained on the cadaver. A demonstration by a photograph followed, showing the chest of a woman who entered the hospital with pleuritis, with effusion on the left side, and displacement of the heart to the right mammillary line, and a photograph of the same patient, thirteen days after the thoracentesis, showing the heart at the medium line. The speaker believed there were several causes that prevented the distention of the pleura in the cadaver, particularly the fact that in not less than 60 per cent. of the cases there were adhesions. Finally, he exhibited an *x*-ray photograph of a patient from whose chest 3,200 c.c. of liquid had been taken, and added that the maximum of liquid injected in the pleura of a cadaver was 1,800 c.c.

Dr. R. Abbe referred to the displacement of the heart in connection with liquid in the pericardium, and cited a case of tumor of the mediastinum, in which there was a marked displacement of the heart.

Dr. L. A. Conner stated that he believed that the results of Dr. Smith's experiments, proving that the slow and gradual distension of the pericardium permits the accumulation of a large quantity of fluid without greatly altering the function of the heart, explained why the function of the heart is but slightly impaired in those cases of pericarditis, in which the formation of the liquid is slow, although its actual quantity may be greater than in other forms of rapid formation with impairment of the function. As to displacement of the heart, he thought that might perhaps depend upon the specific gravity of the liquid which sometimes causes the heart to be lifted toward the chest's walls, and sometimes, instead, pushed downward.

Dr. J. Ewing suggested that perhaps the volume of the heart and the elasticity of the pericardium had a marked influence on the position of the organ and on the quantity of the liquid that the pericardium contained.

Dr. J. S. Thacher said that Dr. Smith's report of the experiments in certain features reminded him of a case of pericarditis reported by Dr. Howland. In both instances extreme extention of the pericardium produced a rounded bulging toward the right with a reentrant angle between the pericardium and the liver.

Dr. J. W. Brannan asked Dr. Smith if he could tell the maximum quantity of fluid found in cases of pericarditis.

Dr. Smith answered that the literature on the subject stated that in one case 2,200 c.c. was found, while in another 3,000 c.c. of exudate was found.

Dr. Brannan asked Dr. Ewing whether cases of rupture of the pericardium had ever been observed.

Dr. Ewing did not recollect any and never measured the quantity of the liquid.

Dr. Smith said that the results of his experiments with liquids of different specific gravity and with gelatinous liquids did not seem to bear out the suggestion that the density of the liquid may have an influence on the displacement of the heart. He believed that he could assert that inflammation and the slow filling of the pericardium might, instead, have a great deal to do with it. It was difficult to determine by experimenting on the cadaver how much distention the pericardium would bear without rupture. The pleura did not stand a rapid distention; live animals did not tolerate the distention of the pleura and the condensation of the lung tissues.

Necrosis of the Extremities in a Child.—Dr. J. S. Thacher presented the history and photographs of a child suffering from necrosis of the extremities, ending in complete loss of the hands and feet with the exception of parts of the fingers of one hand. This case presented an unusual series of exacerbations and remissions of circulatory disturbances in the extremities—of peripheral syncope, congestion, asphyxia, and necrosis. The surfaces at different times became pale or cyanosed or bright red or dark red or black; sometimes hot, at other times cold; with irregular exacerbations and remissions and variations from one phase to another, resulting from time to time in death and loss of tissue. At times tissue apparently beyond the possibility of recovery would suffer only a very superficial loss and at times would gradually resume its normal appearance. But ultimately both feet and one hand were lost, with the adjacent third of the leg or forearm, and portions of the fingers of the other hand. The patient was a negro child, under observation at the Roosevelt hospital for over a year. On admission she was 19 months old. On the previous day she complained that the right leg had been bitten, and a small red spot was noticed by the mother just above the ankle and the ankle and foot were swollen. Later in the same day the child complained that the other foot had been bitten and this foot was found to be swollen and blue. On admission both feet were swollen to the ankles and tender and moderately hot. Two days later the left foot was blue and a few hours later normal in color. The following day both feet were blue and an almost black discoloration appeared on the extensor surfaces of the first three fingers of the right hand. After this the changes spoken of above came and went in a startling manner in all four extremities, also in mild degree over both patellæ and on the pinna of the right ear. The child evidently experienced but little pain, being usually happy and playing with her toys, except when the parts were dressed or the doctors approached her bed. During the summer the stumps granulated, healed, and except for the absence of the lost parts, the girl seemed to be quite well, and gained in weight. At the time of this report she has just returned to the hospital with a little fever and reappearance of discoloration in the stumps. Early in her stay in the hospital she was given a long and generous treatment with iodide and inunctions of mercury, but her chief improvement occurred after this was stopped. In her previous history nothing of importance was learned except that she had had a cold through the previous summer. On admission there were moderate signs of rickets—epiphyses enlarged, abdomen prominent and head square in shape. There were also a few scattered, indurated papules on the face and on the right leg. The blood vessels appeared normal to palpation. The pulsation in both radials, the left posterior tibial and left dorsalis pedis were easily palpable and the vessel walls did not seem to be thickened. The coagulation time of the blood was determined at 3½ minutes. The Wassermann reaction was positive. From this specific reaction and the disastrous outcome it was thought that there must be organic changes in the shape of endarteritis at least partially obliterating, but from the repeated remissions and temporary recoveries, apparently complete, there was evidently a large spastic element, as in Raynaud's disease.

Dr. A. A. Smith asked whether there were signs of syphilis.

Dr. THACHER answered that the evidence of syphilis was a positive Wassermann reaction, and that no corroboration was obtained from the history, except in the report of a prolonged cold during the previous summer; no stigmata were discovered, except rather poor nutrition and some small papules on the skin.

Dr. L. A. CONNER inquired as to the condition of the arteries.

Dr. THACHER answered that on palpation the vessels appeared to be normal, that even the pulsation of the dorsalis pedis of one of the feet could be felt. No microscopic examination of the tissues was made, the parts lost being necrotic.

Dr. C. L. DANA said that the general opinion of neurologists now was that cases of Raynaud's disease or symmetrical gangrene were due to vascular conditions and were not due to neurotrophic influences. While the angiospasm might produce whitening of the fingers it did not cause actual gangrene.

Dr. F. P. KINNICUTT stated that in a case of Raynaud's disease which he had the sections seemed to prove that it was a disease of the vessels, not a nervous disease.

Dr. J. EWING, on request of Dr. Dana, said that he had never seen a case like the one described.

Dr. KINNICUTT said that the case reported by Dr Thacher, in view of the age of the patient was one of great interest. In the light of anatomical studies of juvenile and presenile spontaneous gangrene, an endarteritis obliaterans, an arteriosclerosis, an obliterating angiothromhosis had been variously described by different observers as the pathological process present.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW HAMPSHIRE STATE BOARD OF MEDICAL EXAMINERS.

January 9 and 10, 1912.

ANATOMY.

1. With what bones does the superior maxillary bone articulate?
2. What muscles flex the fingers? Give method of attachment of ligaments of the same.
3. Describe fully the peritoneum.
4. Give location of apex beat, and area of dullness of the normal heart.
5. State fully the method of exit of the nerves from the spinal cord through the foramina in the vertebral column.
6. Describe the ligamentum nuchæ.
7. Enumerate and describe the pectoral muscles.
8. Give origin, course, termination, and branches of brachial artery.
9. Bound and give contents of popliteal space.
10. What tissues are severed in reaching an appendix by the right semilunaris incision?

PHYSIOLOGY AND HYGIENE.

1. Give the normal temperature of the body and two physiological reasons for increased temperature.
2. What is the physiological function of lymph and chyle?
3. Name the physical properties of normal urine.
4. Describe the normal and abnormal motor processes of the stomach.
5. What is Wallerian degeneration? How may it be made use of in studying the course of a tract of nerve fiber?
6. Describe the causes for each step in the passage of oxygen from the atmospheric air to the tissues.
7. What are the healthful preservatives for foods?
8. What diseases should be reported to the board of health, and why?
9. What are the sources of bacteria in milk, and how would you control?
10. What are the physical and chemical characteristics of healthful water?

CHEMISTRY.

1. Explain the difference between a (*a*) solid, (*b*) liquid, (*c*) gas.
2. (*a*) Define capillary attraction. (*b*) Why is it so called? (*c*) Mention some familiar examples.
3. What is electrolysis?
4. What is the composition of baking powders? How are they adulterated? What is their mode of action?
5. Define chemical affinity (chemical force, or attraction, chemism), and give example.
6. Describe the purification of water by distillation and by filtration.
7. What is the effect of diluting tincture of iodine with water, and what practical application is drawn therefrom?
8. What is the action of KHO when taken internally, and what antidotes should be used?
9. Why is zinc sulphate incompatible with the vegetable astringents?
10. In what parts of the body does uric acid occur, and in what form does it exist?

PATHOLOGY AND DIAGNOSIS.

1. Name and describe the germ of syphilis.
2. Give the probable cause and symptoms of calculi of pancreas.
3. Describe a case of Rocky Mountain spotted fever and mention its probable cause.
4. Describe the gonococcus and the method of staining for microscopical examination.
5. Give the causes and symptoms of hemothorax.
6. Give the symptoms and pathology of elephantiasis.
7. Describe a case of Hodgkin's disease and give its pathology.
8. Give the symptoms of disease of the coronary arteries.
9. Describe a case of hay fever and mention some of its probable causes.
10. Give the symptoms of brain tumor.

THERAPEUTICS.

1. What do you understand by Cheyne-Stokes respiration, and under what conditions may it occur?
2. Give the etiology and treatment of acute sciatica.
3. Describe, briefly, the conditions that would lead you to diagnose chronic interstitial nephritis, and give your treatment.
4. What symptoms would lead you to diagnose gastric ulcer and what would be your treatment?
5. What is Bell's palsy and what pathological conditions may produce it?
6. Give the symptomatology and treatment of tetanus.
7. Give the therapeutics of ergot and the symptoms of acute and chronic ergotism.
8. Give the therapeutics of chloral hydrate and the symptoms of a toxic dose of the drug.
9. Under what conditions would you expect enlargement of the spleen?
10. Give the symptoms of acute pancreatitis.

OBSTETRICS.

1. Describe the change in position which the uterus undergoes during pregnancy.
2. What is "morning sickness," when does it begin, how long does it generally continue, and what are its causation and treatment?
3. What are the danger signals of impending eclampsia?
4. What are the symptoms of an inevitable abortion?
5. What are the dangers to the mother during the second stage of labor?
6. Symptoms and conditions leading you to diagnose death of the fetus.
7. How can you distinguish between first and subsequent pregnancies?
8. Give indications calling for podalic version.
9. What conditions of the mother might be mistaken for pregnancy?
10. Treatment of placenta prævia.

SURGERY.

1. Describe a method of reduction of a dislocation of the inferior maxillary bone.
2. What is a Colles' fracture? How would you treat it?
3. What are sources of wound infection?
4. What do you understand by primary and secondary shock?
5. Describe intravenous saline transfusion and give dangers of the operation.
6. How and where would you trephine for cerebral hemorrhage?
7. What do you understand by complete operation for mammary cancer?
8. Describe operation for gallstones.
9. Describe Bassini's operation for inguinal hernia.
10. Give the differential diagnosis of pelvic peritonitis and impaction of feces

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEW HAMPSHIRE STATE BOARD OF MEDICAL EXAMINERS.

January 9 and 10, 1912.

ANATOMY.

1. The *superior maxillary bone articulates with:* Frontal, ethmoid, nasal, malar, lacrymal, inferior turbinate, palate, vomer, and its fellow of the opposite side; sometimes, also, with the sphenoid.

2. *Muscles that flex the fingers:* Flexor sublimis digitorum, flexor profundus digitorum, flexor minimi digiti, lumbricales, and interossei. For method of attachment of their ligaments, see Cunningham's "Anatomy" (1909), pages 341, 342, and 340; or Gray's "Anatomy" (1910), pages 476, 477, and 494.

3. See Cunningham's "Anatomy" (1909), page 1097; or Gray's "Anatomy" (1910), page 1244.

4. The *apex beat of the heart* is in the fifth left intercostal space, about 3¼ inches from the median line.

The *area of complete cardiac dullness* is included between a line drawn from the center of the sternum on a level with the fourth costal cartilage, to the apex of the heart, and a line drawn from the same point down the lower third of the mid-line of the sternum. Below, this area merges into the liver dullness. (From Gray.)

5. See Cunningham's "Anatomy" (1909), page 607; or Gray's "Anatomy" (1910), page 1017.

6. "The *Ligamentum nuchæ* is a fibrous membrane which, in the neck, represents the supraspinous and interspinous ligaments of the lower vertebræ. It extends from the external occipital protuberance to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina (fascia nuchæ), is given off, which is attached to the external occipital crest, the posterior tubercle of the atlas, and the spinous process of each of the cervical vertebræ, so as to form a septum between the muscles on each side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head." (Gray's *Anatomy.*)

7. See Cunningham's "Anatomy" (1909), pages 323 to 326; or Gray's "Anatomy" (1910), pages 456 to 462.

8. See Cunningham's "Anatomy" (1909), page 830; or Gray's "Anatomy" (1910), page 642.

9. BOUNDARIES OF THE POPLITEAL SPACE. *Externally, above:* By the biceps. *Externally, below:* By the plantaris and external head of the gastrocnemius. *Internally, above:* By the semimembranosus, semitendinosus, gracilis, and sartorius. *Internally, below:* By the inner head of the gastrocnemius.

Contents: Popliteal artery and vein, external and internal popliteal nerves, termination of external saphenous vein, small sciatic nerve, articular branch from obturator nerve, lymph glands, and loose adipose tissue.

10. Skin, fascia, linea semilunaris, subserous areolar tissue, and peritoneum.

PHYSIOLOGY AND HYGIENE.

1. The *normal temperature* of the body is between 98° and 99° F.

Two physiological reasons for increased temperature: Muscular exercise, and ingestion of food.

2. *Function of lymph:* (1) It conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

Function of chyle is to absorb nutrient material (chiefly fat) from the intestine and pour it into the blood stream for distribution.

3. *Normal urine* is a yellowish fluid, secreted by the kidneys, to the amount of about 1200 to 1500 c.c. daily; specific gravity, about 1015 to 1025; acid reaction (due to acid sodium phosphate); it has a characteristic odor, and a salty taste.

4. See Gray's "Anatomy" (1910), page 1280.

5. *Wallerian degeneration:* "When a nerve is divided the first result is a loss of its function. Inasmuch as each nerve-fiber develops from a cell which later nourishes it, if the connection between the two is severed the nerve-fiber undergoes Wallerian degeneration, and in the case of a nerve which is made up of nerve-fibers the whole nerve undergoes this change. This degeneration consists, in the case of medullated nerves, in the death of the axis-cylinder, the breaking up of the medullary sheath into drops of myelin, which are later absorbed, and the multiplication of the nuclei of the primitive sheath. In non-medullated nerves the only result is the death of the axis-cylinder. Degeneration begins very soon after the section—within a day or two—and throughout the entire severed portion of the nerve at the same time. Thus the course of a nerve, or a collection of nerves, may be traced throughout its entire extent. These changes are believed to be due to the severance of the nerve from its trophic center. If an anterior root of a spinal nerve is divided, the distal end, being separated from the gray matter of the cord which is its center of nutrition, undergoes degeneration, while the end which remains connected with the cord retains its integrity. If a posterior root is divided between the cord and the ganglion, the degeneration takes place between the cord and the ganglion; while if divided below the ganglion, the degeneration takes place in that portion separated from the ganglion, showing that the ganglion is the nutritive center for the posterior root." (Raymond's *Physiology.*)

This method is made use of in studying the course of a tract of nerve fibers, as follows: "Sections of the cord in which the degeneration has taken place are stained with Marchi's solution; the degenerated fibers stain black, while the other portion remains practically unstained. A tract in which this degeneration takes place below the injury or point of section is a *descending tract*, and the degeneration is a *descending degeneration;* while a tract in which the process occurs above the lesion is an *ascending tract*, and the change, an *ascending degeneration.*" (Raymond's *Physiology.*)

6. "The oxygen in the various under-mentioned media has the following partial percentage pressures of an atmosphere:

Atmospheric air	20.96	per cent.
Alveolar air	18.00	"
Arterial blood plasma	14.00	"
Tissues of the body	0.00	"

What then takes place is this: The oxygen (being a fluid) flows from the place of high pressure to the place of low pressure, and hence diffuses down from the inspired atmospheric air into the alveoli. From the alveoli it now passes through the thin endothelial lining of the alveolus, and the thin endothelial lining of the capillary into the blood plasma. It continues to accumulate in the blood plasma until it has a partial percentage pressure of 14 per cent. of an atmosphere, and it then begins to combine with hemoglobin in the red-blood corpuscles, and so the partial percentage pressure of the oxygen in the blood plasma falls below 14 per cent. of an atmosphere. More oxygen now passes into the blood plasma, raising the partial percentage pressure once more to 14 per cent., and then more oxyhemoglobin is formed. Finally, in this way, nearly the whole of the hemoglobin is converted into oxyhemoglobin. The oxygen passes again from the blood plasma (the place of high pressure) to the tissues (the place of low pressure). In this way its partial percentage pressure in the blood plasma becomes less than 1 per cent. of an atmosphere, and therefore at once the oxyhemoglobin breaks up into oxygen and hemoglobin. This oxygen, passing into the blood plasma, raises its partial percentage pressure once more to 14 per cent. of an atmosphere, and then oxygen begins once more to pass to the tissues from the blood plasma, and oxyhemoglobin to be broken down into oxygen and hemoglobin." (Lack's *Introduction to Physiology.*)

7. *Healthful preservatives for food* are: Drying, exclusion of air and exposure to cold.

8. *Diseases to be reported to the board of health:* Measles, German measles, scarlet fever, smallpox, chickenpox, typhus, relapsing fever, croup, diphtheria, typhoid, Asiatic cholera, tuberculosis, plague, tetanus, anthrax, glanders, epidemic cerebrospinal meningitis, leprosy, trachoma, suppurative conjunctivitis, puerperal septicemia, whooping cough, yellow fever, malaria and any other diseases that may be ordered by the board of health.

Why? (1) To prevent the spread of such diseases, and so to preserve the health of the community; and (2) because neglect to report the same will render the physician liable to penalty.

9. *Sources of bacteria in milk:* The milk itself; the animal from which the milk is obtained; the surface of the udder, the hands of the milker, the cans and containers, the water used for washing the cans or for adulterating the milk, and dirt from any extraneous source.

Control can only be obtained by cleanliness, constant and rigid inspection, with prompt punishment for infraction of sanitary rules.

10. *Characteristics of a good (drinking) water:* (1) It should be clear and limpid. Cloudy and muddy waters

should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water. (From Bartley's *Chemistry.*)

CHEMISTRY.

1. A *solid* is a form of matter in which the relative positions of the molecules are fixed and constant. In a *liquid* the molecules glide past each other and the substance assumes the form of its container. In a *gas* the molecules tend to get away from each other and to occupy a greater space. In a *solid* both volume and form are definite; in a *gas* both volume and form are indefinite; and in a *liquid* the volume is definite and the form is indefinite.

2. *Capillary attraction* is the force which causes fluids to rise through very fine tubes or through the pores of a loose material. The term is derived from the Latin *capillaris*, which means *like a hair;* and capillary attraction is so called because it is best exhibited in fine tubes like hairs.

3. *Electrolysis* is the process of electrical conduction accompanied by the separation of the constituents of the electrolyte, or the decomposition of a chemical compound by passing an electric current through it. The primary products of electrolysis are called ions; those which separate at the positive electrode or anode are called anions; those which separate at the negative electrode or cathode are called cations.

4. *Baking powders*, when pure, should consist of cream of tartar, sodium bicarbonate, and a little flour. *Adulterations* employed are: Alum, acid calcium phosphate, potassium chloride, ammonium carbonate. Baking powders *act* by the decomposition of the $NaHCO_3$ by the cream of tartar, with sudden liberation of CO_2, minute bubbles of which permeate the dough and increase its porosity. (From Scott's *State Board Chemistry.*)

5. *Chemical affinity* is that force which unites atoms together to form molecules; hence, it is the force which unites the two atoms of hydrogen and one atom of oxygen in the molecule of water, H_2O.

6. *Distillation* consists in vaporizing the water and subsequently condensing it by means of cold, and then collecting. By this means water is obtained chemically pure. *Filtration* effects the separation of all particles of undissolved suspended matter, without any alteration of substances that are held in solution.

7. The addition of water to the modern tincture of iodine has no effect beyond diluting it; this is due to the presence of potassium iodide. In the absence of this latter, an insoluble precipitate would be formed. The "practical aplication" to be drawn is, obviously, not to add water or anything else to any substance without knowing what the result will be.

8. Potassium hydroxide acts as a caustic, disintegrates the tissues, and may corrode or perforate the stomach. It is a corrosive rather than a poison. Antidotes are: Dilute vinegar, neutral oils, milk.

9. Zinc sulphate is incompatible with the vegetable astringents, because a mixture of the two would cause a precipitate.

10. Uric acid occurs in the urine, in calculi, in chalky deposits or tophi in the joints of the gouty, in the blood, liver, and spleen. It occurs chiefly as the disodic salt.

PATHOLOGY AND DIAGNOSIS.

1. The germ of syphilis is the *Treponema pallidum*, also called the *Spirochæta pallida*. It is a slender spirillum, with regular turns, the curves varying in number from three or four to twelve or even twenty; it is about 4 to 20 mikrons long, actively motile, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

2. See French's "Practice of Medicine" (1910), page 880; or Osler's "Practice of Medicine" (1909), page 580.

3. See French's "Practice of Medicine" (1910), page 452; or Osler's "Practice of Medicine" (1909), page 368.

4. The *Gonococcus* is a diplococcus with a special predilection for the mucous membrane of the urethra and vagina. It is sometimes found on the conjunctiva. The appearance is that of two coffee beans; the gonococcus is found in the pus cells, stains with ordinary anilin dyes, but not by Gram's method. It is aërobic, and can be cultivated on human blood serum; it will not grow on gelatin, agar, bouillon, or potato. It was discovered by Neisser.

To demonstrate *gonococci:* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismark brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain

5. HEMOTHORAX. *Causes:* Pleurisy (particularly when tuberculosis, cancer, or scurvy, is also present), wounds of chest wall, rupture of an aneurysm, fracture of ribs.

Symptoms: The same as in pleural effusion; see French's "Practice of Medicine" (1910), page 707; or Osler's "Practice of Medicine" (1909), page 645.

6. See Rose and Carless' "Surgery (1911), page 361; or Da Costa's "Surgery" (1911), page 1247.

7. See French's "Practice of Medicine" (1910), page 533; or Osler's "Practice of Medicine" (1909), page 738.

8. See French's "Practice of Medicine" (1910), page 622; or Osler's "Practice of Medicine" (1909), pages 823 and 841.

9. See French's "Practice of Medicine" (1910), page 657; or Osler's "Practice of Medicine" (1909), page 594.

10. See French's "Practice of Medicine" (1910,) page 1136; or Osler's "Practice of Medicine" (1909), page 989.

THERAPEUTICS.

Cheyne-Stokes respiration "is a condition in which the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again. It may occur in tubercular meningitis, cerebral hemorrhage, embolism, thrombosis, aneurysm of basilar artery, uremia, heart disease, etc." (Hughes' *Practice of Medicine.*)

2. See French's "Practice of Medicine" (1910), page 1030; or Osler's "Practice of Medicine" (1909), page 1039.

3. See French's "Practice of Medicine" (1910), pages 927, 930, and 932; or Osler's "Practice of Medicine" (1909), pages 697 and 700.

4. See French's "Practice of Medicine" (1910), pages 765, 767, and 768; or Osler's "Practice of Medicine" (1909), pages 473, 476, and 477.

5. See French's "Practice of Medicine" (1910), page 1042; or Osler's "Practice of Medicine" (1909), page 1019.

6. See French's "Practice of Medicine" (1910), pages 415 and 416; or Osler's "Practice of Medicine" (1909), pages 259 and 261.

7. ERGOT. *Therapeutic indications:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headache, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

Acute ergotism. "In a large dose ergot acts as a gastro-intestinal irritant, causing nausea and vomiting, gastralgia, colic, thirst, and purging. It slows the heart, raises the arterial tension greatly, dilates the pupils and produces pallor, vertigo and frontal headache. It stimulates the contraction of unstriped muscular fiber, especially affecting the sphincters and causing contraction of the sphincter of the bladder, making micturition difficult if not impossible. It produces cerebral and spinal anemia, a great fall of the body-temperature, coldness of the surface, tetanic spasms, and violent convulsions."—(Potter's *Materia Medica*, etc.)

Chronic ergotism "occurs in two forms, the convulsive and the gangrenous—either usually excluding the other. The convulsions are tetanoid spasms of the flexor muscles, the uterus, the intestinal fibers, and the muscles of respiration, ending in coma and death by asphyxia. The gangrenous form begins with coldness and numbness of the

limbs, formication of the skin all over the body, loss of sensibility and abolishment of the special senses, bulke of blood and ichor, followed by dry or moist gangrene of the lower extremities, buttocks and other parts, epileptiform convulsions, coma and death. Autopsies show changes in the posterior columns of the cord, resulting probably from spinal anemia." (Potter's *Materia Medica*, etc.)

8. CHLORAL HYDRATE. *Therapeutics:* It is used as a hypnotic and antispasmodic; it is useful in mania and delirium tremens; as a gastric antiseptic and sedative, also in epilepsy and neuralgia; it is a useful antipruritic, and is a good application for sores and ulcers; it is the antagonist in strychnine poisoning.

Symptoms of a toxic dose are: Deep sleep, muscular relaxation, lowering of body temperature, and abolition of reflexes and sensibility.

9. *Causes of enlargement of the spleen:* "*Excessive chronic enlargement* is most frequently due to leukemia, splenic anemia, or chronic malaria; lesser degrees may be met with in cirrhosis of the liver, rickets, pernicious anemia, passive congestion, or actual portal obstruction. *Acute enlargement* is most often encountered in septicemia, malarial fever, typhoid and typhus, erysipelas, acute miliary tuberculosis, tuberculous peritonitis, cerebrospinal meningitis, smallpox, diphtheria, scarlet fever, relapsing fever, infaret, plague and certain other tropical diseases. (Green's *Medical Diagnosis.*)

10. See French's "Practice of Medicine" (1910), page 876; or Osler's "Practice of Medicine" (1909), page 574.

OBSTETRICS.

1. See Jellett's "Midwifery" (1910), page 213; or Hirst's "Obstetrics" (1909), page 182.

2. See Jellett's "Midwifery" (1910), pages 234 and 475; or Hirst's "Obstetrics" (1909), page 187.

3. See Jellett's "Midwifery" (1910), page 617; or Hirst's "Obstetrics" (1909), page 630.

4. See Hirst's "Obstetrics" (1909), page 277.

5. *Dangers to the mother during the second stage of labor* are: Syncope, hemorrhage, rupture of uterus, eclampsia.

6. *Symptoms of death of the fetus* during the later months of pregnancy are: Cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements cease, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time crepitus of its cranial bones may be elicited.

7.

PRIMIPARA.	MULTIPARA.
The fourchet is present.	The fourchet is missing.
The perineum is tense and deep.	The perineum is relaxed and probably torn.
The labia are in apposition.	The vulva is frequently patulous.
The vagina possesses tonicity, and is rough and rugous, with a granular feel.	The vagina is relaxed and smooth.
The cervix is long, soft, and conical; the os is undilated.	The cervix is large, cylindrical, short, not so soft, and probably lacerated; the os is patulous.
The abdomen is full, rounded, tense, and resisting to the touch.	The abdominal walls are relaxed and non-resisting to the touch; the skin is loose and wrinkled.
Dark, purplish-red striæ appear late in pregnancy.	The striæ may be both white and livid, the former being present from the beginning of pregnancy.
The breasts are full, firm, and sensitive to pressure.	The breasts are flabby, pendulous, and non-sensitive to pressure.
The nipples are usually small and undeveloped or even inverted.	The nipples are large and well developed.
Striæ are absent upon the breast.	Striæ are frequently to be found.

—(From Dorland's *Obstetrics.*)

8. See Jellett's "Midwifery" (1910), page 1048; or Hirst's "Obstetrics" (1909), pages 827 and 830.

9. *Conditions of the mother which might be mistaken for pregnancy:* Ascites, ovarian cysts, uterine fibroids, other pelvic tumors, subinvolution of uterus, pseudocyesis, hematometra, amenorrhea, obesity, over-distended bladder.

10. See Jellett's "Midwifery" (1910), page 716; or Hirst's "Obstetrics" (1909), page 577.

SURGERY.

1. See Rose and Carless' "Surgery" (1911), page 910; or Da Costa's "Surgery" (1911), page 669.

2. See Rose and Carless' "Surgery" (1911), pages 518 and 521; or Da Costa's "Surgery" (1911), pages 581 and 583.

3. *Sources of wound infection:* Air; water; patient's skin, hair, or clothing; hands of surgeon, assistants, or friends; instruments and dressings; solutions; insects.

4. *Shock* is the name given to a sudden and general depression of the vital powers, due to some strong stimulation (such as injury or emotion), acting on the vital centers in the medulla and producing vasomotor paralysis. Shock is *primary* when the symptoms appear promptly; it is *secondary* when the symptoms don't appear for several hours (often observed after railway accidents, intoxication, etc.).

5. See Rose and Carless' "Surgery" (1911), page 278; or Da Costa's "Surgery" (1911), page 465. *Dangers of the operation are:* Entrance of air into the vein, dyspnea, cyanosis, sepsis.

6. See Rose and Carless' "Surgery" (1911), pages 776 and 759; or Da Costa's "Surgery" (1911), pages 804 and 842.

7. See Rose and Carless' "Surgery" (1911), page 964; or Da Costa's "Surgery" (1911), page 1433.

8. See Rose and Carless' "Surgery" (1911), page 1077; or Da Costa's "Surgery" (1911), page 1036.

9. See Rose and Carless' "Surgery" (1911), page 1100; or Da Costa's "Surgery" (1911), page 1131.

10. See Rose and Carless' "Surgery" (1911), pages 983, 986, 990, and 1137; or Da Costa's "Surgery" (1911), pages 971 and 1004.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 9
Arizona*	Ancil Martin, Phoenix	Phoenix	April 1
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 14
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	San Francisco	April 2
Colorado	David A. Strickler, Empire Building, Denver	Denver	April 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 12
Delaware	J. H. Wilson, Dover	Dover	June 18
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	April —
Florida*	I. D. Fernandez, Jacksonville	Jacksonville	May 6
Georgia	C. T. Nolan, Marietta	Atlanta / Augusta	May —
Idaho*	O. J. Allen, Bellevue	Boise	April 2
Illinois	J. A. Egan, Springfield	Chicago	April —
Indiana	W. T. Gott, Crawfordsville	Indianapolis	July 9
Iowa	G. H. Semner, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	
Kentucky	J. N. McCormac, Bowling Green	Louisville	
Louisiana	A. B. Brown, Cusach's Bldg. New Orleans	New Orleans	May 30
Maine	F. W. Searle, Portland	Portland	Mar. 12
Maryland	J. McP. Scott, Hagerstown	Baltimore	June 18
Massachusetts*	E. B. Harvey, State House Boston	Boston	Mar. 12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 11
Minnesota	W. S. Fullerton, St. Paul	Minneapolis	April 2
Mississippi	S. H. McLean, Jackson	Jackson	May 14
Missouri	Frank B. Hiller, Jefferson City	Kansas City	
Montana*	Wm. C. Riddell, Helena	Helena	April 2

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE POCKET ATLAS OF THE FUNDUS OCULI, with Note and Drawing Book. Text by G. LINDSAY JOHNSON, M.A., M.D., F.R.C.S., with drawings from life by Arthur W. Head, F. Z. S. 205 pages; illustrated; paper; price $2.50 net. F. A. Hardy & Company, Publishers, Chicago.

ANNUAL REPORT OF THE DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK. 1909. 395 pages; cloth. Board of Health, Publishers.

HANDBOOK OF MENTAL EXAMINATION METHODS. By SHEPHERD IVORY FRANZ, Ph.D. 165 pages; paper; price $2.00. The Journal of Nervous and Mental Disease Pub. Company, Publishers, New York.

ANNALI DI MEDICINA NAVALE E COLONIALE. 1911. Vol. II. 650 pages; paper. Direzione e Amministrazione Ministero Della Marina, Publishers, Rome.

STUDIES IN PSYCHIATRY. Vol. I. By members of the New York Psychiatrical Society. 222 pages; illustrated; paper; price $2.00. The Journal of Nervous & Mental Disease Pub. Company, Publishers, New York.

BLAIR'S POCKET THERAPEUTICS. By THOS. S. BLAIR, M.D. 373 pages; leather. The Medical Council Company, Publishers, Philadelphia.

THE TRAGEDY OF CORIOLANUS. By STUART P. SHERMAN, Ph.D. 189 pages; cloth; price $.35 net. The Macmillan Company, Publishers, New York.

WAR LETTERS OF WILLIAM THOMPSON LUSK, Captain, Assistant Adjutant-General U. S. Volunteers 1861-1863. Afterward M.D., LL.D. 304 pages; cloth.

THE TAYLOR POCKET CASE RECORD. By J. J. TAYLOR, M.D. The Medical Council Co., Publishers, Philadelphia.

SECOND REVIEW OF SOME OF THE RECENT ADVANCES IN TROPICAL MEDICINE, HYGIENE, AND TROPICAL VETERINARY SCIENCE. SUPPLEMENT TO THE FOURTH REPORT OF THE WELLCOME TROPICAL RESEARCH LABORATORIES AT THE GORDON MEMORIAL COLLEGE, KHARTOUM. By ANDREW BALFOUR, M.D., B.Sc., F.R.C.P., D.P.H., and Capt. R. G. ARCHIBALD, N.B, R.A.M.C. 448 pages; cloth. Bailliere, Tindall & Cox, Publishers, London.

MANUAL OF PRACTICAL PHYSIOLOGY. By JOHN C. HEMMETER, M.D., Ph.D., LL.D. 223 pages; with 55 illustrations; cloth; price $2.50 net. P. BLAKISTON'S SON & COMPANY, Publishers, Philadelphia.

SIGHT TESTING FOR THE GENERAL PRACTITIONER. 5th Edition. By F. DAVIDSON. 84 pages; illustrated; cloth; price 2/6 net. F. Davidson, Publisher, London.

TRANSACTIONS OF THE AMERICAN HOSPITAL ASSOCIATION. 13th Annual Conference. Held at New York City, September 19, 20, 21 and 22, 1911. Vol. XIII. 512 pages; illustrated; paper. Published by the Association.

THE CRIMINAL AND THE COMMUNITY. By Dr. JAMES DEVON. 348 pages; cloth; $1.75 net. JOHN LANE COMPANY, Publishers, New York.

TRANSACTIONS OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION FOR THE YEAR 1911. Vol. XXVII. 410 pages; illustrated; cloth. Published by the Association.

THE ACCESSORY SINUSES OF THE NOSE IN CHILDREN. By Prof. Dr. A. ONODI. 102 specimens reproduced in natural size from photographs. Price, cloth, $7.00. William Wood & Company, Publishers, New York.

MATERNITY PRIMER. By A. H. F. BARBOUR, M.D., LL.D. 165 pages; illustrated; price, cloth 75c. net. William Wood & Company, Publishers, New York.

DENTAL ANESTHETICS. By WILFRED E. ALDERSON, M.D. 100 pages; price, cloth, $1.25 net. William Wood & Company, Publishers, New York.

PLEURISY. By ALEX. JAMES, M.D., F.R.C.P.E. 243 pages; illustrated; price, cloth, $2.25 net. William Wood & Company, Publishers, New York.

SURGERY AND SOCIETY. By C. W. SALEEBY, M.D., F.R.S.E. 305 pages; price, cloth, $2.50 net. Moffat, Yard & Company, Publishers, New York.

THE ORIENTATION OF BUILDINGS OR PLANNING FOR SUNLIGHT. By WILLIAM ATKINSON. 139 pages; illustrated; cloth. John Wiley & Sons, Publishers, New York.

PRINCIPLES OF HUMAN NUTRITION. By WHITMAN H. JORDAN. 450 pages; illustrated; price, cloth, $1.75 net. The Macmillan Company, Publishers, New York.

KLINIK FÜR PSYCHISCHE UND NERVOSE KRANKHEITEN. Vol. VI, No. 4. By Dr. R. SOMMER. 384 pages; paper; price 12 M. Carl Marhold, Publisher, Halle.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 2, 1912.

	Cases	Deaths
Tuberculosis Pulmonalis	598	203
Diphtheria and Croup	322	32
Measles	1269	24
Scarlet Fever	419	17
Smallpox	2	—
Varicella	299	—
Typhoid Fever	34	5
Whooping Cough	52	1
Cerebrospinal Meningitis	9	6
Malarial Fever	—	—
Totals	3,004	288

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended March 1, 1912.

CHOLERA

Places	Date	Cases	Deaths
India: Madras	Jan. 14–20	18	14
Indo-China: Saigon	Jan. 2–8	197	145
Turkey in Asia: Aleppo	Jan. 28–Feb. 3	11	5

YELLOW FEVER

Mexico: Puerto Mexico (Coatzocoalcos)	Feb. 28	..	1
7 cases in the lazaretto from S. S. *Ikalis* from Guayaquil.			
Salina Cruz	Feb. 4-7	..	..
Venezuela: Caracas	Jan. 1–15	8	8
La Guaira	Feb. 27	..	..
Present.			

PLAGUE

China: Hongkong	Jan. 7–13	3	2
Hawaii: Honakaa	Feb. 25	2	2
India: Bombay	Jan. 14–20	6	4
Karachi	Jan. 14–20	1	1
Mauritius	Dec. 1–7	7	6
Peru:			
Departments—			
Callao	Oct. 1–21	1	..
In November 1 case, in January 3 cases with 2 deaths.			
Chiclayo	Oct. 1–21	12	4
Chosika	Oct. 1–21	1	1
Lambayeque	Oct. 1–21	3	..
Libertad	Oct. 1–21	8	..
Lima	Oct. 1–21	13	6
Straits Settlements: Singapore	Jan. 1–6	2	2

SMALLPOX

Austria-Hungary: Bohemia	Jan. 14–20	1	..
Krain	Jan. 14–20	7	..
Tyrol	Jan. 14–20	1	..
Brazil: Pernambuco	Dec. 15–31	..	77
Canada: Montreal	Feb. 11–17	7	..
Ottawa	Feb. 4–17	15	..
Quebec	Feb. 10–17	16	..
Toronto	Feb. 4–10	1	..
Victoria	Feb. 4–10	1	..
Chile: Santiago	Nov. 1–30	*685	343
Valparaiso	Jan. 14–20	..	..
Present.			
China: Hongkong	Jan. 6–13	27	19
Shanghai	Jan. 15–21	..	1
France: Paris	Jan. 21–27	5	2
Germany	Jan. 28–Feb. 3	1	..
Great Britain: London	Jan. 28–Feb. 3	2	..
India: Bombay	Jan. 14–20	16	12
Madras	Jan. 14–20	8	6
Italy: Leghorn	Feb. 4–10	4	..
Messina	Jan. 1–31	..	1
Turin	Jan. 29–Feb. 4	1	..
Japan: Kobe	Jan. 22–28	1	1
Jan. 20, one case from S. S. *Suveric* from Hongkong.			
Java: Batavia	Jan. 7–13	3	1
Mexico: Aguascalientes	Feb. 5–11	1	..
Chihuahua	Jan. 22–Feb. 11	30	15
Magdalena	Feb. 7	..	..
62 cases present.			
Mazatlan	Feb. 13	..	..
33 cases in the lazaretto.			
Mexico	Jan. 1–13	12	7
Tampico	Jan. 10–Feb. 10	..	4
Portugal: Lisbon	Jan. 28–Feb. 3	2	..
Siberia: Omsk	Jan. 1–31	7	..
Spain: Madrid	Jan. 1–31	..	2
Valencia	Jan. 1–31	24	..
Straits Settlements: Singapore	Jan. 1–6	2	..
Switzerland: Canton—			
Oberwalden	Jan. 14–20	1	..
Teneriffe: Santa Cruz	Jan. 28–Feb. 3	..	4
Turkey in Europe: Constantinople	Jan. 29–Feb. 4	..	8
Venezuela: Caracas	Jan. 1–15	..	2

IMPORTANCE OF DISEASE IN PLANT AND ANIMAL EVOLUTION.

By R. G. ECCLES, M. D.,

BROOKLYN, N. Y.

IN *Amœba proteus* we have one of the simplest animal forms known to man. It is a single independent cell possessing the power of reproducing its kind generation after generation, for countless ages, in an unbroken series. In *Gonium sociale* we have another protozoan a trifle higher in the scale of being. It is composed of a group of four cells linked together as a unit organism. The four united cells live, move, and act as a single healthy individual. It is one of the very simplest of polycellular organisms, of which man is one of the most complex. This persistent social union of four cells, and no more, repeating itself generation after generation, probably resembles the original organism which in the very distant past took this first step on its way toward man from the ameba. It gives us early evidence of the existence in cells of some sort of regulatory mechanism by which, while under identical conditions of temperature and nutrition, they can divide and redivide at definite intervals, and with clock-like precision, into groups having certain fixed ratios of units like themselves. This regulating mechanism we call heredity. No such number-regulating mechanism exists in the amebæ for they only produce single, ununited cells. From Gonium upward this mechanism shows an ever-increasing complexity that becomes perfectly bewildering long before reaching man. To what are we indebted for this first step in the construction of a cell machine having time regulating qualities? Geddes and Thompson suggest that such colonies "originated pathologically in all probability," because, as they say, "the protozoa cannot be accused of any prevision of future advantage in remaining clubbed together in cooperation, nor, indeed, credited with much primitive altruism in so doing."[1] These lowly organisms could have had no more voluntary control of their variations than we have had of ours, as for instance, in the producing of the furrows on the tips of our fingers. These furrows, without our volition, have varied so much that we can each be told by them from every other being on the earth. Change—variation—is seen everywhere and the molecules out of which amebæ are built can be no exception to the general rule. Indeed we have the strongest kind of chemical evidence that they are very variable so that the wonder really is as to how the ameba's mechanical structure is able to keep them from varying immensely more than they do. For them to vary in ways that would lead to the cohering of groups of two or more amebæ into single colonies might or might not prove fit. A grouping that would provide a means of hindering parasitic pilfering would often save their lives. It would have the selective value necessary to cause survival. In such a union there would be strength. The too rapid multiplication of such fit forms, however, would in time necessitate a spreading out into new regions in search of new food supplies. This must bring them into contact with new foes able to attack in new ways. The old fitness might now prove inadequate and death have a harvest among them. A new variation that would lead to a larger colony would supply additional strength and resisting power. If, instead of dividing into groups of four, clinging together till ready to form new colonies and then separating to form other groups of four, some stray *Gonium sociale* had failed to separate its cells at maturity and clung together in groups of four times four we would have had another step in favorable variation that would bring more strength, *i.e.* fitness. In *Gonium pectorale* we have just such a sixteen-cell group.[2] Another step still higher up in this process of colony formation is seen in *Magosphæra planula*. It, however, belongs to a different genus and could not be connected by direct descent with Gonium. Haeckel tells us that "The fully-formed body is a gelatinous sphere, with its wall composed of thirty-two to sixty-four ciliated homogeneous cells; it swims about freely in the sea. After reaching maturity the community is dissolved. Each cell then lives independently for some time, grows, and changes into a creeping ameba. This afterward contracts and clothes itself with the structural membrane. The cell then looks just like an ordinary animal ovum. When it has been in this condition for some time the cell divides into two, four, eight, sixteen, thirty-two, and sixty-four cells. These arrange themselves in a round vesicle, thrust out vibratory lashes, burst the capsule, and swim about in the same magosphæra-form with which they started."[3] In Prof. Kofoid's *Pleodorina illinoisensis* we have an American protozoon which likewise exists as a thirty-two-celled colony. In it we discover what may be an example of the most primitive form of another type of variation that is of great theoretical importance. Should future investigation show it to be, as we suspect it is, a variation toward sterility, *i.e.* inability to produce in kind, then it is an illustration of the beginning of a series of variations that have been the marking milestones along the entire pathway of advancing organic evolution. Four of the thirty-two cells are very much smaller than are any of the other twenty-eight. They are grouped together in the front of the moving colony, *i.e.* the part facing forward during locomotion. The twenty-eight are fertile, but no one has reported seeing any of the four front cells multiplying. They are supposed to be non-fertile, *i.e.* sterile. If we

compare them with the much higher form of cell-colony, *Volvox globator*, we will find a similar kind of grouping in which the fertile cells can be distinguished from the non-fertile ones, and see that the relations that are important to our argument are the same in each. In *Volvox globator* colonies the number of cells per colony varies from a minimum of 1500 to a maximum of 22,000 according to the variety. In these, says Prof. Calkin, "differentiation has gone so far that the cells if separated, with the exception of the reproductive elements, cannot live. The individuals forming the peripheral layer form the sterile vegetative or somatic cells of the aggregate. A few of these cells, which reproduce asexually, are found upon the inside of the peripheral layer, which protects them like a mantle."[5] Of the same organism (Volvox) Lankester's Zoology tells us that the cells are arranged in the form of a sphere and that "the sphere comprises two differently constituted hemispheres. The trophic (food providing) hemisphere is that which is directed forward during locomotion. . . . The other hemisphere is the generative hemisphere, in which the oogonidia (female germ cells), antherogonidia (male germ cells), and parthenogonidia (self-fertile germ cells), are chiefly formed."[6] The fact that the front half of the sphere is sterile, with only a few self-fertile cells hidden below the peripheral cells, shows that we have probably here a condition similar to but greater in extent than that seen in Pleodorina. In the latter it is four front cells as against twenty-eight rear ones, while in the former it is equal numbers of rear and front ones, or nearly so. In Pleodorina it is as 1 to 7 while in Volvox it is as 1 to 1. In both the rear cells are fertile. In both the front cells are food seekers. To the believer in natural selection these two organisms present a number of interesting problems. How came they to have two kinds of cells? What could have caused the dwarfing seen prominently in Pleodorina front cells. Evolutionists must believe that these two types of cells were once alike. Selectionists must hold that the variation was due to some sort of life and death struggle in which the variation proved to be of life and death value. How could such dwarfage save the colony from extinction? Why was there less danger in the rear than in the front? Why did the front cells of Volvox, and most likely of Pleodorina as well, change the sterile cells while the rear ones retained their fertility? If subjected solely to the laws of chance the fertile and sterile cells should have been mixed together in all sorts of ways, in all parts of the colonies. The fact of their not being mixed shows that the front cells had to vary in order to survive and to permit of the survival of the colonies. No consistent selectionist can draw any other conclusion. The front cells would be the cells most, and first, exposed to danger from adhering parasites. Flying from the danger would not rid the cells of their acquired infection. The parasites would stick and multiply to the injury or destruction of the host. As all parasites have a selective affinity for certain kinds of foods to the exclusion of others—each to its own particular kind—some sort of quantitative or qualitative change would become imperative in the front cells if the menace became great. The tempting (attracting) molecules within the cells must become fewer, disappear entirely, or change their attractiveness into repulsion in order to save such threatened colonies from extinction. In the evolution of Pleodorina, whatever other variations may have occurred, there was evidently a reduction in the numbers of molecules. The selectionist must hold that inasmuch as the disappearance of these molecules was of selective value, and inasmuch as parasitism had perhaps something to do with it, the attractive molecules most likely disappeared in bringing about the change. This supplies us with a probable explanation of the dwarfage of the front cells. As the mechanism governing cell multiplication resides within the cell this loss of substance from the front cells would be expected in some way to affect it. If the eliminated attractive molecules happened to be the ones taking part in cell multiplication this would account for the induced sterility. Let us then see if this hypothesis is borne out by other facts. The diminished number of certainly fertile cells in Volvox over Pleodorina—fifty per cent. as compared with ten per cent.—would seem to make it at least theoretically clear that the danger to the former must have been materially greater than to the latter. The hidden position of the self-fertile cells of the anterior hemisphere confirms this conclusion. As we ascend the scale of living things the germ cells gradually disappear, in the way here indicated, until the front and periphery are wholly divested of them and until they have become located in positions of maximum safety from parasites. The germ cells (fertile cells) finally disappear from every place of great exposure as if seeking to hide themselves behind and beneath the soma cells (sterile cells). In the vertebrates the evidences of their proportional reduction and of their hiding proclivities are particularly pronounced. In the lower Protozoa we found the germ cells to be 100 per cent. of the total. In the vertebrates they are an exceedingly small fraction of one per cent. of the total. In the Coelenterates we have an intermediate condition much like that of the vegetable kingdom. A study of the latter gives us a clear understanding of the way in which the division of soma plasm from germ plasm has been gradually brought about.

"The somatic tracks," says De Vries, "have obviously developed phylogenetically from the secondary germ tracks. Not suddenly, however, and at a leap, but quite gradually. The loss of the power of reproduction makes them such. By this means, however, only an adaptation, and no intrinsic difference is conferred."[7] Again he says that "germ cells and somatic cells do not present any qualitative contrast in the plant kingdom. They are the extremes of a long line of qualitative differences. This law I regard as one of the most important results of the consideration of vegetable cell pedigrees. Sachs, Strasburger, and others have pointed out the importance of this law."[7] Bowen, in agreement with these others, has shown that the sex organs of flowering plants, instead of being metamorphosed leaves, have more likely evolved from the flowerless plants by a process which he says "may, perhaps, be called with more propriety 'sterilization,' a term which indicates clearly what has probably been a prevalent phenomenon in the course of descent of vascular plants."[8] De Vries shows the orderly way in which sterilization has occurred when he tells us that "In the celled pedigree of one-celled organisms and of homoplastids all the twigs are primary germ tracks. In the next higher plants primary and secondary germ tracks are to be distinguished and, the more highly the organism is differentiated, the more are the latter pushed into the background. . . . In the case

of the vascular plants, most of the tissue cells, at least when fully developed, can without doubt no longer produce the species."[9] The fact that the greater the differentiation the more of the structure of an organism is sterile is of great significance. Animals being much more highly differentiated than plants the bodies of animals contain a vastly larger ratio of soma plasm to germ plasm than do plants however highly differentiated. Why this incessant recession of germ plasm with the progress of evolution? Why are there no cases of an increased ratio of germ over soma plasm *pari passu* with high development? Why such solicitude for the safety of germ plasm at the risk of endangering soma plasm? It all looks as if the struggle for existence, as related to tissue cells, has always been a struggle against parasites.

That parasites are still at work endangering and destroying germ cells has been proven by Giard and many others.[10] Cases of what are called parasitic castration are of common occurrence and have been reported from numerous genera and orders of both plants and animals. Prof. H. B. Ward says that "When a parasite develops in an organism it causes sterility in its host. Such parasitic castration may be direct or indirect. The first case is met when the parasite destroys directly by mechanical means, or for its nutrition, the genital glands of its host. Parasitic castration is indirect when the producing parasite is not directly in relation with the genital glands, but in some other part of the body of the host. Parasitic castration may also be temporary and then disappear when the parasite is suppressed. The modifications caused by parasitic castration affect the genital organs, the secondary sexual characters and the sexual instincts of the infested animals; it may be partial to any degree and may exert the same influences on the secondary sexual characters as age, or as artificial castration. Each one of the sexes loses more or less its characteristic attributes and tends to acquire in the same degree those of the opposite sex."[11] Indirect parasitic castration is a fact having immense importance for the future of evolutionary philosophy. That parasites in lungs, liver, kidneys, or intestines can, by aid of something they introduce into the circulation, damage or destroy the germ cells of their hosts, even to the extent of rendering them permanently sterile, is a fact the importance of which it would be hard to overestimate. That various degrees of sterilization can thus occur is also important. According to Prof. Ward indirect castration can be produced by intestinal worms as well as by bacteria, protozoa, and the like. Prof. Wheeler, in an article in the *Journal of Experimental Zoology*, cites a large number of cases of parasitic castration of bees, wasps, ants, beetles, and crustaceans. He tells of a nematode (worm) which infests bees rendering the queens sterile so that sometimes they "have not a single mature egg in their ovaries." All queens that these worms infest are found on microscopic examination to have normal organs, although they may be quite sterile. The sterility is due to indirect causes. Such bees cannot found colonies. Among the cases he cites is one of earwig beetles (Forficula) that when infected by gregarines have a shortening of their forceps. The trained eye can tell the sick beetles from the well ones by noting the lengths of their forceps.[12] Prof. Geoffrey Smith relates a case of bacterial castration in a "thoroughbred" rooster which he bought for breeding. In two weeks it sickened, stopped crowing, comb and wattles shriveled and lost color, and the tail drooped. On killing, dissecting, and examining microscopically and otherwise, he found that it had been suffering from avian tuberculosis. The testes were reduced in size but uninfected, their appearance being that of an immature bird a few weeks old. There were no spermatozoa. He pronounced the case "an instance of the parasitic castration caused by a bacterial infection of a vertebrate host."[13] Prof. Ewart, at a meeting of the Zoological Section of the British Association, told of some blue-rock pigeons which he had received from India that were infected with bird-malaria (Halteridium). Those with numerous parasites were infertile on mating, those with very few mated successfully, one with few mated with another with many produced offspring, but they all died before leaving the nest. One bird that was at first sterile, because of the many parasites that it carried, "mated successfully as soon as the number became greatly reduced."[14] In Bulletin 30 of the Committee of One Hundred on Public Health, of the American Association for the Advancement of Science, we are told that "one of the most constant effects of gonorrhea in women is permanent and irremediable sterility. . . . Noeggerth found in 81 gonorrheal women 49 entirely sterile. In 80 sterile marriages Kehrer found 45 caused by inflammatory changes of gonorrheal origin."[15] Many cases are due to obstructions, such as obliteration of the ducts of the epididymus, and occlusion or constriction of the lumen of the Fallopian tubes in salpingitis. In mild attacks, however, particularly in males, indirect castration plays an important part. A study of the semen in victims of this disease reveals, under the microscope, that only part of the spermatozoa show vitality. This is called relative oligospermia. In more severe cases the number of living spermatozoa is pronouncedly reduced. This is known as serious oligospermia. In still more severe cases there are no motile spermatozoa. This is denominated azoospermia. In very severe cases life-long sterility results through total inability to produce semen. Such cases are probably due to direct inflammation of the testes and the condition is known as aspermia.[16] The graded degrees in the reduction of viable spermatozoa indicate the presence within the circulation of a cytotoxin—a cell poison. It evidently acts in proportion to its concentration. An artificial cytotoxin of this kind—a spermatoxin—has been produced, that kills spermatozoa when sufficiently concentrated. We are told by Ehrlich that "Landsteiner, Metchnikoff, and Moxter succeeded in producing an immune serum (spermatoxin) against spermatozoa."[17] As evidence of the kinship between the molecules of spermatozoa and of soma cells "Metchnikoff found that by the proper method of immunization he could produce spermatoxin in animals devoid of testicles."[18]

What a flood of new light the facts here presented cast upon the *process* of natural selection. One serious objection long urged against Darwin's theory is that the age of the earth would have to be well-nigh eternal, so far as our pigmy intellects are able to compass immense millions of years, to meet its requirements. "Remember what natural selection is," says Prof. Kellogg, when endeavoring to fairly represent the contention of the anti-Darwinian, "the saving of one or ten thousand because in the struggle for existence the variations of the one or ten are of sufficient advantage to

have a life-or-death-determining value."[19] "Geologic time," he urges, "seems too short to give selection time to do its work." He qualifies this with the supposition that the newer argument for the earth's probable age as deduced from the possible action of radium, might easily extend the time limit. De Vries says that "Many thousands of millions of years were considered to be the smallest amount that would account for the development of life on earth."[20] His doctrine of leaps (mutations) he seems to think does away with the long time requirement. Until mutationists are able to solve the riddle of these leaps, by the discovery of an adequate cause therefor, no one can seriously maintain that the time requirement of biological evolution has been shortened a particle. With Prof. Poulton the writer is inclined to hold that "mutation without selection may be left to those who desire to revive Special Creation under another name."[21] Vast as are the millions of years allotted to the earth's age by geologists, it seems a beggarly pittance compared with the real time requirements, if the saving of chance variations and the premature destruction of adult forms that are unable to survive the "tooth and claw" struggle with the environment, constitutes the whole of natural selection. Let the reader, at this late date, re-read Herbert Spencer's paper on "The Inadequacy of Natural Selection"; let the time problem dominate his mind as he reads and he will be pretty sure to conclude that either there is something wrong with this limited notion of natural selection or that Spencer has certainly proven its inadequacy. It is, most assuredly, inadequate in the cases he has cited. So staggering became the problem to Spencer's broad grasp that he seemed confident that no amount of time could surmount the difficulties. "Either there has been inheritance of acquired characters or there has been no evolution" was the triumphant climax which he defiantly hurled at Prof. Weismann and which the latter gentleman was powerless to refute.[22] Either there has been inheritance of acquired characters or the miracle of Special Creation must be evoked to solve the riddle, is what this means. And this confession came from Herbert Spencer when the tide had begun to turn in the minds of our best naturalists against any belief in the inheritance of acquired characters. The facts needed to solve the problems which he raised were not then all known and no such meaning had been suspected as residing within those that were known. Parasitic selection of proteins and parasitic castration of hosts, together with our present knowledge of immunology, had raised no suspicion of a broader Darwinism that looks to cells and molecules as the principal struggling and surviving units.

The long ages during which germ plasm has been gradually receding from danger into positions of protection behind soma plasm points to the possibility that much, perhaps most, of the destruction of unfitness and survival of fitness has been the destruction of unfit germ cells and survival of fit germ cells, as such, rather than the destruction, always, of adult forms. If spermatozoa, ova, and parthenogonidia are and have been affected by disease in all sorts of degrees, through the countless years of the past, their fit must have been subject to continuous survival and their unfit to incessant extinction before leaving their producing organisms. If this is true then it follows that natural selection must have gone on within the body at a speed far in excess of anything that could possibly be brought about by the destruction of adult forms. In the case of motile spermatozoa if they were greatly injured, even though not killed, their motility would be impaired and they thereby handicapped in the race for the ovum with their more favored fellows. Only such as sufficiently resisted blood-borne poisons could have a fair chance of becoming a directing agent in the development of a fetus. Their great waste in vertebrate conjugation cannot be accounted for on the basis of natural selection unless it is of selective value. It is of selective value if the apparent profligacy is a distinct utility in the direction here indicated. The wastefulness of wind-borne pollen is evidently a necessity in the requirements of wind fertilized plants. It is of selective value inasmuch as an economy of production of such pollen would mean the extinction of many or most of these plants. In highly specialized, insect-fertilized plants no such waste occurs. This evidence of parsimony, where germ-plasm bears a much higher ratio to soma-plasm than in vertebrates, is evidence of the conserving influence of natural selection. Waste, as such, is extinguished. Why, then, such apparent waste among vertebrates unless natural selection picks out the variants among the spermatozoa? If the discharged spermatozoa are of varying degrees of fitness, or varying degrees of vitality, owing to their having been exposed to cytotoxins, *i.e.* cell poisons, then the apparent excess is understandable. That artificially produced cytotoxins will kill and injure them has already been pointed out. That they are damaged by bacterial and protozoal cytotoxins has also been shown. That they show different degrees of susceptibility is also known. Why then should we doubt that they may be the agents of natural selection in bringing about evolutionary changes? The American Text-Book of Physiology tells us regarding spermatozoa that "upon the basis of observation on several individuals Lode computes the average production per week as 226,257,000 and in the period of thirty years, from twenty-five to fifty-five years of age, the total production is 339,385,500,000."[23] Here, then, are over 339 billions of possibilities for chance variations to occur within each male individual during a single lifetime. Among all these there should be some that would change toward fitness. Disease can maim and ruthlessly destroy this number of billions of unfit and still leave, per individual, 385 millions of favorable—resisting—variants. Their vigor would enable them to more rapidly reach the ova after injection. The fittest of these fit would be the final survivors—the progenitors of the future. If variations occur among them in all directions possible for spermatozoa to vary in accordance with the doctrine of chance, some of these 339 billions of chances should show variations in the progressive direction. If 339 billions of generations of human beings had to perish in order to supply the same chances for survival of the fit variants what a tremendous draft would have to be made upon time in order to secure as much change as might thus occur within the limits of a single lifetime. If every generation has supplied a similar number of chances how vast a total the myriads of years between us and ameba has given. To crowd the selections of 339 billions of generations into each single generation and to multiply these with as many generations as lie between us and our ameba ancestor will give the difference in selective power between the two conceptions of the way natural selection may be doing its work. Quite likely

Lode's estimate is in excess of the numbers found in many individuals, and we do not know just how the numbers may recede backward toward the ameba with its single chance, but, with the most liberal allowance for these, the total will remain overwhelmingly vast. In the ova the chances for variations are pronouncedly smaller. Meltzer tells us that "the ovary of the new-born female child possesses between 100,000 and 400,000 eggs, and at the time of puberty there are still about 30,000 ova ready to enter upon their possible mission."[24] Disease toxins can reach and damage these just as they reach and damage spermatozoa, but the numbers to be acted upon are here materially less. Where too many are destroyed the woman becomes sterile. The so-called nursing cells appear to be unfit ova and their bodies supply the surviving ova with part of their pabulum. The best resisting ova thus appear to survive and the least resisting to perish.

The injury to soma cells as well as to germ cells, from cytotoxins, is well known. The discomfort, fever, and other symptoms due to the poisonous products of pathogenic microbes in most diseases are familiar even to laymen. That the cells of different kinds are damaged and killed without coming into immediate contact with the attacking parasites is not so well known. "In the majority of diseased conditions," says Dr. Dickson, "various degenerate phenomena, due to the action of the bacterial and other toxic substances producing or accompanying the disease, are of practically constant occurrence in the cells of the bone-marrow, and similar changes may also be found in many of the cells of the circulating blood. These degenerative conditions may be more marked in the nuclei of the cells, or again they may chiefly affect the parts of the cell are almost invariably affected."[25] Miss Reed asserts that following active phagocytosis "neutrophiles first react to the presence of bacilli or a toxin by some metabolic change, which is shown by increase in the number of lobes in the nucleus," and that "these reacted cells break down or are used up in the blood."[26] That the red cells of the blood are subject to destruction in a number of diseases in which anemia occurs has long been believed by physicians. Prof. Wells declares that "the hemolysis (destruction of red cells) of the acute febrile diseases is readily explained by the demonstrable hemolytic property of the products of the organisms that cause them, such as streptocolysin, staphylolysin, etc. (various bacterial cytolysins). . . . In malaria, although the parasites enter and destroy the capsules in which they live, yet this alone does not account for all the blood destruction of the disease, for the amount of anemia is quite without relation to the number of parasites to be found. There is good reason to believe that the plasmodia produce hemolytic substances that are discharged into the serum."[27] The various cell toxins having often, perhaps always, a so-called lytic or dissolving power upon cells and tissues, puts meaning into the "unusually high rate of self digestion" which Flexner says occurs "in organs removed from individuals who succumb to typhoid fever and other infectious diseases" and explains why "the softening and the wasting of tissues is most striking when these are under the influence of protoplasmic poisons."[28] The same explanation will apply to the fact mentioned by Calkins that "a widespread effect of protozoa is the lysis set up by their presence in cells and tissues." He says "this was clearly worked out by Councilman and Lafleur in the case of amebic dysentery where the parasites penetrate the submucosa where they cause the cells to jellify and degenerate. Similar destructive changes are brought about by the organisms of trachoma, of rabies, and of smallpox."[29] That this dissolving or lytic effect injures blood cells in varying degrees and produces its chief visible effects within the nucleus has been shown by Dr. Dickson, of the Pathological Department of the University of Edinburgh. He tells us that the changes produced "may in general be divided and classified—according to the manner in which they affect the nucleus—into the two great divisions karyorrhexis or fragmentation of the nucleus, a change frequently preceded or accompanied by swelling of the nucleus and solution of its chromatin and followed by its disappearance by solution in the cytoplasm; and karyolysis characterized by swelling of the nucleus and solution of its chromatin."[30]

This attacking of the nuclei of cells by the cytotoxins is very significant in view of the fact that the nucleus is now generally conceded to be the seat of the cell's hereditary qualities. De Vries tells us that "the hereditary characters are contained in the nuclei, as was first declared by Haeckel, and later demonstrated by O. Hertwig, and for plants by Strasburger. This important law forms, for the present, the basis of the whole anatomical theory of heredity, and is recognized as such by all investigators."[31] Prof. Wilson says that the chromatin, which has been mentioned above, "is the nuclear substance *par excellence*, for in many cases it appears to be the only element of the nucleus that is directly handed on by division from cell to cell, and it seems to have the power to produce all the other elements."[32] Preparatory to cell division the chromatin gives rise to separate rod-shaped bodies known as chromosomes. Prof. Conn asserts that "It is evident that the chromosomes form the part of the cell which contains the hereditary traits handed down from parent to child. This follows from the fact that the chromosomes are the only part of the cell which in the fertilized egg is derived from both parents. Now the offspring can certainly inherit from each parent, and hence the hereditary traits must be associated with some part of the cell that is derived from both."[33] Microscopic research appears to sustain this reasoning inasmuch as "Boveri found in the development of Ascaris (a thread worm) that the germ-cells, which preserve all the characteristics of this species, also preserve all the chromatin of their chromosomes, but that in the body cells, which undergo differentiation, the chromosomes undergo diminution."[34] Prof. E. B. Wilson, commenting upon this, says that "from the outset the progenitor of the germ-cells differs from the somatic cells not only in the greater size and richness of the chromatin of its nuclei, but also in its mode of mitosis (indirect nuclear division); for in all those blastomeres (first division cells of a fecundated egg) destined to produce somatic cells a portion of the chromatin is cast out and into the cytoplasm, where it degenerates, and *only in the germ cells* is the sum total of the chromatin retained."[35] G. S. Dodds' study of Lophius (angler fish) has shown that in this genus "the nucleus of germ-cells is noticeably larger than that of other cells" and that with progressive differentiation "the nucleus of the somatic cells is becoming continually smaller while that of the germ

cells remains of constant size. Prof. Conklin tells us that during the cleavage of the egg of *Crepidula plana* (a bonnet-shell mollusk) the average nuclear growth "is not more than 5 per cent. to 9 per cent. for each division up to the 32-cell stage and it may fall as low as 0.3 per cent. to 1 per cent. for each division after that stage; and in every case it falls far short of a doubling, or increase of 100 per cent. for each division." He tells us that "the average growth in volume of chromatin from the 2-cell to the 32-cell stage is about 8 per cent. for each division period, being about the same as the growth of the nucleus as a whole." He further adds that "the chromosomes become individually smaller as cleavage progresses, and in general small nuclei give rise to smaller chromosomes than do large nuclei."[37] If we next consider the evidence from plant and animal experiments we find it also confirmatory of Prof. Conn's reasoning. Professors McDougal, Gager, and others have shown that the introduction of dilute solutions of poisonous substances into the interiors of the ovaries of plants, when the solutions do not destroy the ovaries or abort the developing seeds, as they do in most cases, has been followed by the production of living seeds that produce plants unlike the parents. The introduction of such solutions into the ovaries of "Rainannia was followed by the production of seeds bearing qualities not exhibited by the parent, wholly irreversible, and fully transmissible in successive generations. Encouraged by this success, a number of reagents were used in the following year, with *Oenethera biennis* (evening primrose), a plant which had been under observation for some time, and with which I (McDougal) was so familiar as to be able to recognize alterations readily. Of the various tests with this plant, one, which had been treated with a solution of zinc sulphate, gave seeds one of which reproduced a plant known to my associates and myself as 'F 206,' which differed so remarkably from the parental form as to be recognizable by a novice."[38] Animal experiments of this kind have not been very successful. Prof. A. P. Matthews has tried some with amino acids, on echinoderms, molluscs, and porifera. He found that impure leucine prepared from horn when in dilute solution, if applied to the eggs of arbacia (sea-urchins) arrests development without killing them. When they are removed to fresh water they develop into all sorts of fantastic embryos.[39]

How much of the effect secured in experiments of these kinds should be attributed to nuclear changes and how much to injured cytoplasm cannot at present be determined. It is most likely that both receive injury and that if both carry hereditary qualities, as some claim, it would be impossible to distinguish between their effects. The evidence in our possession all points toward chromatin as the chief, probably the sole, center of heredity-control. The protein molecules, however, all take part as building stones of the structure and are the substances that the chromatin must, somehow, direct heredity through. Says Prof. J. Loeb: "One would naturally think first of definite chemical compounds as the bearers of hereditary qualities."[40] Prof. Guyer puts the same idea into these words: "That there is a physicochemical basis of heredity and that it is, if not exclusively, at least fundamentally, bound up in the proteins of the germ-cells, we know for certain."[41] Prof. von Noorden states the case thus: "The protein molecule, just as the cell and protoplasm can transmit and hand down its form and specific energy to a newly formed molecule. Its form is constant, while its contents, the C,H,N, and O atoms, may alter. One part of the problem dealing with the transmission of vital properties—in fact, a most important because a fundamental one—is the transmission of the protein molecule."[42] Conklin tells us that "The substance which forms the nuclear sap is absorbed by the nucleus from the cell body throughout the whole of the resting period, only to be thrown out into the cell body again at the end of that period. Consequently the nuclear sap is no more a nuclear constituent than a protoplasmic one, belonging to both nucleus and protoplasm (cytoplasm). . . . There is good reason for believing that the nuclear sap contributes to the nourishment and growth of the chromatin and linin, and that it in turn receives substances from these."[43] Does it not seem from this that there is constant reciprocity between nucleus and cytoplasm in which each gives and takes from the other? The proteins must be made somewhere, either in the cytoplasm or the nucleoplasm. If chromatin is the director of heredity and the proteins the carriers of the same, may it not be that protein molecules are products built up by chromatin? One chemical authority has asserted that "we cannot arrive at any other conclusion than that the nucleoproteids (old name) are the agencies by which amino-acids are built up into cell-plasm."[44]

Chemical analysis of the nucleus shows it to be composed of what chemists now call nucleoprotein and out of this the chromatin of the microscopist is probably constructed. This identification of nucleoprotein and chromatin supplies still another argument in behalf of the theory that loss of chromatin causes differentiation in tissues. Prof. Hill tells us that "Neucleoprotein is most abundant in plain muscle and least abundant in voluntary or striated muscle; cardiac muscle occupies an intermediate position in this respect. . . . Plain muscle is the least and voluntary muscle the most differentiated."[45] This simply means that in the differentiation of voluntary muscle from plain muscle there occurred a lessening in the amount of chromatin. In the passing on of the inheritance-producing stuff certain kinds of nucleoprotein molecules were left out and their absence created the difference between plain and striated muscle. There is still another chemical fact that adds materially to the evidence. "Whenever," says Mann, "the other amino-acids increase in number and complexity arginin diminishes in amount."[46] As arginin is the one distinctive amino-acid that is more abundant in chromatin protein than in any other protein and as increase in number and complexity of other amino-acids is a sign of differentiation in proteins, then it follows that with increased differentiation there must be, according to this chemical evidence, decrease in nuclear material—decrease in chromatin. Thus chemistry and microscopy join each other in supplying evidence toward proving that all great tissue changes which have occurred in plants and animals during the ages of the past have been due to successive losses of chromatin (nucleoprotein) from the tissues as they have differentiated from each other. Deductive logic, based upon the principle of natural selection, appears to show that the only reasonable explanation for these successive losses of chromatin is that the protein molecules in its structure, and in the structure of the cytoplasm, have been under incessant selective destruction by para-

sites of many kinds ever since the dawn of polycellular life.

This explanation casts a flood of light upon many obscure histological problems. It shows us why it is that "differentiation in any direction terminates the possibility of differentiation in any other direction," as has been asserted by Prof. Minot. It shows us why it is, as he also asserts, that "in accordance with this law we encounter no instances, either in normal or pathological development of the transformation of a cell of one kind of tissue into a cell of another kind of tissue, and (why) further we encounter no instances of a differentiated cell being transformed back into an undifferentiated cell of the embryonic type with varied potentialities." It supplies the basic chemical explanation of why, as Minot again declares, "we must look upon each step in the process of differentiation as establishing narrower limits for future changes."[47] This same explanation puts an added meaning into the facts that "Epithelial tissues (epiblastic and hypoblastic) can only be converted into other forms of epithelial tissues, one form of mesoblastic into another form of mesoblastic. Epithelium and gland cells, for example, never become converted into bone or cartilage, or *vice versa*, while, again, it may be laid down that among epiblastic and hypoblastic tissues, on the one hand, and mesoblastic tissues on the other, there is no new development or metaplasia of the most highly specialized tissues from less specialized tissues; a simple epithelium cannot in the vertebrate give rise to the more complex glandular tissue, or to nerve cells; in regeneration of epithelium there is no new formation of hair roots or cutaneous glands. The cells of white fibrous connective tissue have not been seen to form striated or even non-striated muscle."[48] Why should we expect to see any such transformations of tissues if the conditions under which they have evolved were such as our array of facts indicate? If germ cells contain a fixed, assorted store of, say, one hundred different kinds of protein-producing chromatin granules, and if, when dividing to form soma cells, only seventy-five kinds are transmitted to the new cells, why should such cells, by multiplication of their seventy-five kinds, and dividing, produce germ cells having one hundred kinds? If the newly formed soma cells divide and produce more highly differentiated soma cells containing only fifty kinds of chromatin granules, why should we expect these last produced cells to be able to reappear identically the same as their seventy-five protein progenitors? A part can never equal a whole, nor can fifty kinds of specific chomatin reappear as seventy-five kinds. If many different kinds of protozoa and bacteria, having as many preferences (chemotactic affinities) as there are kinds of chromatin, should for countless ages seek to feed upon these or on the molecules they produce, what ought we to expect would happen under conditions as we know them? In places where one kind of these foes was dangerously numerous, or in times in which it became so, would we not expect great destruction of the tissue containing the particular protein it was attracted to, if that tissue was greatly exposed? Would not natural selection preserve the organism that left out the tempting chromatin from that exposed tissue? Let another parasite with a different choice then become dangerously plenty in the same region as that organism and would not natural selection kill off all that failed to drop out of its exposed tissue the tempting morsel? Let this continue to be the order of events for numberless generations and would we not get a large variety of tissues with different powers of resisting parasitic foes? We have seen that attacking parasites possess the ability of not only injuring and killing cells that are near or in contact with them, but cells at the most remote parts of the body. This indirect injury we have learned is due to specific cell poisons—cytotoxins—produced by the parasites. These toxic substances can damage some kinds of cells more than others.

The cells, however, are able to retaliate, not only by neutralizing the parasite's poisons, but also by themselves producing counter poisons. Every such poison is more or less specific for the particular kind of invader. Indeed, so perfect has become the mechanism of production that no kind of alien protein can be introduced into the circulation of any of the higher vertebrates, in unusual amounts, without the appearance in the blood of poisons that can kill the animal or microorganism or damage the organ from which the protein came. Ehrlich tells us that "the investigation of numerous authors have shown that by injecting animals with any kind of foreign cell-material cytotoxic substances can be produced directed exactly against the material used for immunization. Thus if a dog is immunized with an emulsion of goose brain it will be found that the dog's serum will be highly toxic only for geese, killing these animals with cerebral symptoms. In the same way we can produce other poisons, hepatotoxins (for the liver), nephrotoxins (for the kidneys), etc."[49] Wells has recounted, in his "Chemical Pathology," the various kinds of experiments pursued in producing leucocytotoxins, endotheliotoxins, lymphatotoxins, nephrotoxins, neurotoxins, and thyrotoxins. He also refers to reports upon epitheliotoxins, spermatotoxins, cardiotoxins, splenotoxins, and syncytiotoxins.[50] Dr. S. P. Beebe has done some of this kind of work in our own country. He has reported, in the *Journal of Experimental Medicine*, that by injecting five successive safe doses of nucleoproteins from dogs into the peritoneal cavities of rabbits, at intervals of six days, and bleeding them eight days later, a cytotoxic serum was secured that when injected into the circulation of dogs was specific for the same organs as those from which the nucleoproteins were taken. He states that he succeeded in this way in producing definite, specific toxins for the liver, when liver nucleoprotein was used, for the kidney when kidney nucleoprotein was used, and for the pancreas when pancreatic nucleoprotein was used. After recounting his experimental results with kidney-cell toxin, he says: "There seems to be no doubt from these findings that this nephrotoxin sets up an acute degeneration of the kidney tissue." Regarding his liver cytotoxin he says: "With the serum made by injecting liver nucleoproteids I have produced very serious lesions of the liver, apparently without causing serious injury to other organs."[51] Prior to his experiments Charrin and other French investigators startled pathologists by results obtained through injecting proteins into pregnant females. "Among the experiments related," says an editorial writer in the *Journal of the American Medical Association*, "is the subcutaneous injection of an emulsion of liver substance in a gravid goat. A total of 84 gm. was injected at various times, equal to two per thousand of the animal's weight. Sixteen days after the last in-

jection she was delivered of a kid that died at once. All its organs were macroscopically sound, with the exception of the liver, which was reduced to a pulp. There were no traces of microbes."[52] In this case the hepatotoxin appears to have been produced in the dam's blood, in response to the injections of liver emulsion. It had to pass into the fetal circulation, reach the fetal liver, exert its specific poisonous effects upon the nucleoproteins thereof, thus killing the cells and, through autodigestion, completing the destruction. Delamere, after wounding the kidneys of pregnant dams is reported as having found that such injury was "followed by hemorrhagic and degenerative lesions in the corresponding organs of the fetus."[53] In such cases as these there would almost certainly be infection of the dam's wounded organs. Following such infection bacteria produced cytotoxins would be certain to appear inasmuch as it is in the digestion battle between cells and parasites that they are produced.

Long before any explanation of such a case as this was possible, Darwin had observed that when mutilations "are followed by gangrene they are apt to be inherited."[54] Here we have an unintentional acknowledgment that without infection injuries do not impress themselves on spermatozoa or ova. He seems to have looked upon such cases as indirect evidence of the inheritance of bodily acquired characters when the fact is that, from a pathological view, they are strong evidence of natural selection. He tells us that "the evidence that accidental mutilations can be inherited is at present not quite decisive; but the remarkable case observed by Brown-Séquard of inherited epilepsy in guinea pigs, caused by an operation performed on the spinal cord, should make us cautious in denying such power."[55] In the case here referred to, and in all subsequent cases in the now celebrated Brown-Séquard experiments, bacterial invasion of the injured parts was practically unavoidable. Prof. Romaines very properly denies the probability of a specific kind of pathogenic microorganism having been responsible for such results. It did not occur to him nor to others that ordinary pyogenic bacteria might be the agencies aiding inheritance through the effects of their cytotoxins upon germ plasm. They are, of course, ubiquitous. The following is Brown-Séquard's summary of his results:

1. Appearance of epilepsy in animals born of parents which had been rendered epileptic by an injury to the spinal cord.

2. Appearance of epilepsy also in animals born of parents which had been rendered epileptic by section of the sciatic nerve.

3. A change in the shape of the ear in animals born of parents in which such a change was the effect of a division of the cervical sympathetic nerve.

4. Partial closure of the eyelids in animals born of parents in which that state of the eyelids had been caused either by section of the cervical sympathetic nerve, or the removal of the superior cervical ganglion.

5. Exophthalmia in animals born of parents in which an injury to the restiform body had produced that protrusion of the eye-ball. This interesting fact I have witnessed a good many times, and seen the transmission of the morbid state of the eye continue through four generations. In these animals, modified by heredity, the two eyes generally protruded, although in the parents usually only one showed exophthalmia, the lesion having been made in most cases only on one of the corpora restiformia.

6. Hematoma and dry gangrene of the ears in animals born of parents in which these ear alterations had been caused by an injury to the restiform body near the nib of the calamus.

7. Absence of two toes out of the three of the hind leg, and sometimes of the three, in animals whose parents had eaten up their hind-leg toes which had become anesthetic from a section of the sciatic nerve alone, or of that nerve and also of the crural. Sometimes, instead of complete absence of the toes, only a part of one or two or three was missing in the young, although in the parent not only the toes but the whole foot were absent (partly eaten off, partly destroyed by inflammation, ulceration, or gangrene).

8. Appearance of various morbid states of the skin and hair of the neck and face in animals born of parents having had similar alterations in the same parts, as effects of an injury to the sciatic nerve.[56]

Thirty years were occupied in performing these experiments. They were independently vouched for by Dr. Dupuy and Prof. Westphal, who had assisted in their production. The epilepsy cases were independently verified by Obersteiner. Prof. Romaines spent some time in France with Brown-Séquard, endeavoring to verify all of them. He was successful with most of them but, in spite of the guidance of Brown-Séquard he was not able to secure all of the results. If the item of infection is of paramount importance this is just what might be expected. To secure the same degree of cytotoxic concentration at every trial could hardly be expected. By repeating and rerepeating the experiments some approach to this would be apt to be secured in a number of cases but not in all.

That the matter of quantitative intoxication is of great importance can be readily inferred, but the seriousness of its importance few realize. "It has been established," says Prof. H. M. Richards, "that many, if not all, classes of substances which exert a toxic action on protoplasm will become stimulating if presented to the cells in sufficiently small doses. Somewhere between an infinitesimally weak solution which produces no reaction, to the toxic dose which kills, there is a stimulative optimum which gives the maximum of reaction. The question is not the possible ultimate lethal effect of these poisons, but how far they may excite the protoplasm to extraordinary activity."[57] Prof. Wells tells us that "Mallory's observations on the phenomena of proliferation and phagocytosis show that the same bacterial products which destroy the cells when concentrated, when sufficiently dilute cause proliferation of similar cells."[58] Prof. Theobald Smith informs us that "it was shown many years ago by Prudden and Hodenpyle, by Straus, and many others that dead, even boiled and washed, bacilli stimulate cell proliferation of a more or less specific type."[59] It is, therefore, evident that while a relatively large dose of a cell poison may injure or destroy the cells, a smaller dose may be distinctly beneficial, stimulating to activity and multiplication. These toxins seem to act much as heat does. An excess kills, while a reasonable amount is beneficial. When acting upon a germ cell the toxin from a local

lesion or disease would, other things being equal, produce effects proportional to the volume of infection. As the toxins are specific, having affinities for special protein molecules of the germ-cell, and not for other molecules of the same cell, different toxins must have different effects upon them. As parasites have preferences for certain kinds of protein molecules, they will attack some somaplasm molecules and not others. As their toxins are adjusted to the kinds of molecules that they attack, acting as amboceptors to the same, these toxins are attracted to such molecules wherever found within the body. Thus it happens that there is softening of many tissues after infections. The same cytotoxins reaching the germ cells by way of the circulation show this affinity there. They stimulate, damage, or destroy the same sorts of nucleoproteins and other proteins in the germ cells as the producing parasites are stimulating, damaging, and destroying in the cells of the body. As all tissues have, through natural selection, gained a considerable degree of resistance toward the great mass of would-be parasites—to some more, to others less—every organism, through youth to maturity, maintains a fair balance of health. At all times, however, they are liable to infection from being exposed to pathogenic microorganisms over which they have acquired little or no resistance, and, what is, perhaps, of more importance, to parasites over which they have, under ordinary circumstances, considerable resistance. We are told that "military surgeons note again and again that though soldiers while in garrison may be free from typhoid fever, they are liable to develop it as soon as they have undergone the strain of maneuvers, although they are stationed in villages where there is no typhoid. * * * Charrin and Rogers" * * * "experimented on white rats, using the bacillus of anthrax and of symptomatic anthrax. The experimental animals were first made to run in a squirrel's cage for several hours till thoroughly tired, and were then injected, control rats being injected with an equal dose. Charrin and Rogers found that the fatigued rats succumbed to the infection earlier than the non-fatigued and that in some cases the latter survived a dose which killed the former in less than twenty-four hours. In one experiment five control rats, inoculated with the virus of symptomatic anthrax, survived, while all of the six fatigued rats inoculated with the same amounts died, three of them in less than twenty-four hours."[60] De Sandro confirmed these results on dogs, rabbits, and guinea pigs. What has been proven true of fatigue is believed to be true of exposure to hunger, to cold, or to any other condition that carries out of the normal. Our resisting powers are at their best only under favorable conditions and deviations from these bring upon us infection from parasites, some of which are now known to be our constant companions through life.

We are told by Prof. T. H. Morgan that "The speed of the hare bears no causal relation to that of the fox. We cannot think of the fox in the sense of a physical environment acting on the germ-cells of hares; yet without the fox the hare would, we feel confident, never have developed the long hind legs."[61] It occurs to the writer that without the fear of foxes, or their likes, the progenitors of hares would not have had to run so hard as to seriously fatigue and cripple themselves. Without the fatigue and crippling they would not have developed inflammations and diseases of the legs such as follow injuries and great fatigue. Without such inflammations and diseases there would not have arisen, within the circulation of these pro-hares, cytotoxins specific toward damaged bone, muscle, tendon, or other leg tissues. Without the cytotoxins there would have been neither stimulation nor damage to spermatozoa or ova or to their specific chromatin, and, consequently, no natural selection among the specific protein molecules eliminating the unfit and preserving and strengthening the fit so that they should be sure to take part in the reconstruction of future legs. The parts of the legs in the pro-hares that hindered effort toward great speed, would be the parts damaged most in every spurt of speed needed to save life. Nerves, muscles, tendons, bones, cartilages would all suffer betimes under excessive strain and fatigue, and would all be subject to injury and inflammation. In exact proportion to the degree of damage to each tissue would be the degree of effect upon the cytotoxin-invaded germ-cells. All tissues, or parts thereof, that favored speed in locomotion would suffer little from the strain and would, therefore, only transmit stimulation. All that by virtue of size, shape, or other form of handicap, hindered speed in locomotion would, on the average, be damaged exactly in the ratio of their hindrances. They would produce great amounts of cytotoxins, because of greater infection, and they would damage the chromatin of the germ cells in a degree corresponding to the extent of their own injury. Qualitatively, too, the damage in both would have a correspondence. The destruction of pro-hares by quick-running, hungry foxes, or animals akin thereto, would, of course, aid in eliminating the unfit, but only to a meagre extent as compared with the destruction of germ-cells. The destruction of adult animals could supply no mechanism for the establishment of the coordination among organs, tissues, cells, and molecules. Dr. F. B. Sumner not long ago said: "If a mechanism exists whereby the germ-cells may be so influenced as to bring about the parallel modification of parent and offspring, such a mechanism would be of exactly the same value for evolution as 'the inheritance of acquired characters' in the old sense."[62] To the writer it appears as if we have in disease just such a mechanism as that to which Dr. Sumner refers. The indications are that it is so accurately adjusted as to be able to respond to every change in the environment that is not wholly overwhelming. It is so minutely adjusted that chemical molecules are its units of fitness. In selecting the fit among these it secures fit cells, in selecting the fit among cells it secures fit tissues, in selecting the fit among tissues it secures fit organs, and in selecting the fit among organs it secures fit organisms. Natural selection when only seen as working solely upon organisms *en bloc*, mystifies the understanding and necessitates some supplementary belief, like that of acquired characters, to help it out. The study of natural selection as it occurs among protein molecules attacked by parasites brings us down to the bedrock of naturalism, banishes metaphysical teleology, shows us that the world and all it contains is a harmonic whole, and extinguishes forever the thought that any part of nature is vile or accursed.

THE RELATION OF PELVIC DISEASE IN WOMEN TO OSTEOARTHRITIC JOINTS.*

By W. A. NEWMAN DORLAND, A.M., M.D.,

CHICAGO

PROFESSOR OF OBSTETRICS IN THE MEDICAL DEPARTMENT OF LOYOLA UNIVERSITY, CHICAGO; VISITING OBSTETRICIAN AND GYNECOLOGIST TO JEFFERSON PARK HOSPITAL, ETC., ETC.

The Pelvic Articulations as True Joints.—In order to comprehend more thoroughly the relationship existing between pelvic disease in women and pelvic osteoarthritis the following axioms should be borne in mind:—(1) It is now clearly recognized that the pelvic articulations are true joints, comprising in their formation all the structures peculiar to a joint. (2) The articulations between the sacrum and ilia are by far the most important joints of the pelvis. (3) When in a state of health motion to a limited extent is a definite part of the normal function of the pelvic joints, and this motion exists irrespective of age or sex unless it be restricted or obliterated as a result of some congenital or pathological condition. (4) There is normally a greater mobility of the pelvic joints in women, although motion is present to a limited extent in men. (5) The normal motion of the pelvic articulations consists of an up-and-down play at the symphysis, and in a tilting or forward and back movement of the sacrum upon the ilia—or the ilia upon the sacrum—the center of motion being a transverse axis situated at about the middle of the sacrum. (6) Symphyseal movement, while frequently more apparent, can occur only in conjunction with motion at the sacroiliac synchondroses. (7) The pubic bones, together with their symphysis, are of comparatively little importance in maintaining the stability of the pelvis, and serve chiefly to afford attachment for muscles and support for the pelvic viscera. This portion of the pelvic girdle may be entirely absent without causing serious inconvenience to the patient, even during pregnancy and labor. (8) Obstetrically considered, motion at the sacroiliac synchondroses is of interest as causing an increase or decrease in the size of the pelvic inlet. (9) If the pelvic articulations are true joints they are susceptible to the same diseases as other joints. (10) Not only are these articulations susceptible to disease, but because of their anatomic peculiarities they are more liable to injury than are most of the other joints of the body. This is true, because the bones are simply apposed, with the axis of the joint perpendicular (as at the symphysis) or very slightly oblique (as at the synchondroses), the articular surfaces being smooth or but slightly irregular. Therefore, the stability of the joints depends almost entirely upon the ligaments and muscles.

Classification of Non-Tuberculous Affections of the Pelvic Joints.—The non-tuberculous affections of the pelvic articulations may be conveniently grouped as follows: (1) Strain and distortion of the symphysis pubis and sacroiliac synchondroses, including that occurring in the course of osteomalacia. (2) Relaxation of the symphysis pubis and other synchondroses. (3) Bacterial invasion of the pelvic articulations other than by the tubercle bacillus. (4) Traumatism of the sacroiliac joints during and after symphyseotomy. (5) Malignant disease of the pelvic joints.

Strain of the Pelvic Joints.—From the brief anatomical description of the pelvic joints already given it becomes evident that strain of these joints is the simplest pathological condition that may be encountered in them. It is, moreover, the commonest of these conditions, and especially so in the sacroiliac synchondroses. Strain of the pelvic articulations will almost inevitably follow depreciation in the muscular or ligamentous tone of the parts, since, as has been noted, the integrity of the joints depends almost entirely upon the soft tissues surrounding them. It is also self-evident that because of this fact "disturbances in the normal approximation of the bones must be more common and result from much less violence than in other

*Read on January 24, 1912, before the Chicago Medical Society, in a symposium on "Surgery for the Relief of Nontuberculous Chronic Joint Diseases."

joints" (Goldthwait, Painter, and Osgood). A prolonged maintenance of one position, as stooping, standing, lying, or sitting, will often result in a strain of the sacroiliac joints. It can hardly be doubted that many of the lumbosacral backaches that distress womankind may be explained in this way. Thus, prolonged dorsal decubitus after childbirth, in protracted illness, or after abdominal section, produces a strain of the sacroiliac ligaments with resultant chronic aches and pains. When it is recalled that the sacral plexuses of nerves rest just anterior to these synchondroses, it is easy to understand how readily these nerves may be impinged upon and irritated by the yielding joints. Referred pains are thereby produced—sensations that are referred to the areas of distribution of the irritated nerves instead of to the actual seat of injury. In this line, Genty has called attention to a form of pelvic strain resulting from sacroiliac relaxation due to the gradual effacement of the lumbar curvature during profound anesthesia. This gives rise to sharp pains in the back which persist for variable periods of time.

Pelvic Disease and Osteoarthritic Joints.—Grave changes in the pelvic bones themselves, as the softening due to rachitis and osteomalacia—the latter generally developing subsequent to a gestation—are responsible for strains and distortions of their synchondroses with consequent backaches and referred pains that become almost intolerable. As interesting in emphasizing the intimate, though imperfectly understood, bond that exists between pelvic disease in women and osteoarthritic joints, the following facts are worthy of note: According to Tyson, the late J. M. Da Costa claimed that rheumatoid arthritis is the form assumed by hereditary gout in the female. It is well known that females are much more liable to this disease than males—especially sterile women and those suffering from uterine or ovarian disease. Garrod collected 500 cases of arthritis deformans, 411 of which were females and but 89 males. The beginning of the menstrual period is a favorite time for the incipiency of the disease—a striking fact in support of this occult interrelationship between pelvic congestion, physiological or pathological, and osteoarthritis.

Tweedy and Wrench, when speaking of osteomalacia and its usual origination during pregnancy, call attention to the fact that the best treatment to insure arrest of the development of the disease is double oöphorectomy, especially in young women—another proof of this same relationship. Save on the ground of an analogy in the functions of the various so-called internal secretions this relationship is not so patent in the remarkable cures of osteomalacia which have been recorded following the daily hypodermatic injection of the extract of the hypophysis (H. Rab) or of from 5 to 15 grams of adrenalin (L. Bernard).

Relaxation of the Pelvic Joints.—The close association which exists between the pelvic articulations and the female pelvic viscera probably cannot be better demonstrated than by the peculiar softening and relaxation of these joints that is so universally noted as occurring physiologically during the latter weeks of gestation, and pathologically in the course of certain grave infections and congestive disorders of the pelvis. Generally, the physiological relaxation of pregnancy is so slight as to escape observation, although it may be definitely measurable. Rarely, the symphyseal relaxation will be so marked that walking becomes difficult or impossible. This relaxation may also be present in the sacroiliac synchondroses, and in both instances the loosening may persist after confinement, resulting in a marked disability in locomotion.

Goldthwait, moreover, emphasizes the fact that to a lesser degree, but appreciable, nevertheless, the same condition of relaxation takes place at each menstrual period, "which," he says, "from a physiological point of view represents a miniature pregnancy." Of course, this relaxation is slight as compared with that of pregnancy, but it is at times definite enough to cause considerable suffering and real disability. Both the menstrual and the gestational relaxation are clearly due to the increased vascularity of the pelvis in all its anatomic parts at these periods of physiological congestion. The relaxation must naturally be more pronounced in the presence of menorrhagia as indicative of excessive pelvic congestion. The symptoms of joint-congestion at these periods are intermittent, appearing with the flow, the pain being slight in most instances and located in the abdomen and small of the back, but at other times amounting to a severe sciatica. This pain is always associated with muscular spasms in the lumbar region, and inability to bend the trunk forward. In some of these cases, Meisenbach states, motion may be felt in the sacroiliac joints without the aid of leverage of the limbs, merely by placing the thumbs upon the sacrum and the fingers upon the ilia.

There is, in addition, a decided pathological side to this question of pelvic articular relaxation. It is probable that in any disease of the pelvic organs in which there is present marked circulatory disturbance the joints become relaxed. The converse of this proposition is, undoubtedly, true, as Goldthwait and others have incontrovertibly shown—namely, "that if the pelvic joints become relaxed as the result of accident or disease, the lack of stability of the pelvic girdle, with the resulting weakening of the support of the pelvic organs, leads to congestive disturbances in these organs, this in turn probably reacting upon the joints, so that until the proper treatment can be instituted there exists a vicious circle of cause and effect." Meisenbach, in his recent able paper, suggestively remarks that "the frequency with which the broad ligaments and round ligaments have to be shortened by gynecological interference is the best example of the yielding of ligaments caused by congestion." A similar change, though to a much less degree, undoubtedly takes place in the pelvic articular ligaments, and the relaxation so produced must of necessity result in a strain of the unsupported joints. The greater the pelvic congestion the greater the vascularity of the joints. Therefore, pelvic tumors, uterine myomata and fibromata and ovarian cysts are very prone to be complicated, to a greater or lesser degree, by this articular change. Some of the severer cases of pelvic relaxation originate at the time of the delivery of a child, especially if the labor has been a difficult forceps extraction. In these patients not infrequently an actual displacement of a sacroiliac joint may occur, and these more chronic cases are accompanied by the same symptoms as occur after the acute sprains. In the cases developing because of pelvic disease the symptoms are precisely the same as those which follow menstrual congestion, save that they do not occur periodically but are more or less constant. A mechanical cause for the joint-

trouble may exist in certain cases in which improper dressing, as tight lacing or pressure from the straight-front corset, has been long persisted in. The same trouble, Meisenbach claims, may follow the improper application of the abdominal binder after labor or abdominal section. Pressure so exerted upon the iliac crests may actually separate the sacroiliac joints instead of coaptating these structures.

The symptoms produced by relaxation of the pelvic joints include restriction in locomotion as well as in the various movements of the spine, and the development of persistent pains in the small of the back, lumbago, sciatica, and pain in the course of the genitocrural nerve. If the cause of these symptoms be recognized early and the proper treatment be instituted, many of the so-called "chronic invalids" will be cured before that deplorable state is reached. These cases are best treated by the application of a leather or plaster jacket which fits tightly over the sacrum and ilia. At the same time walking or other movement of the limbs should be limited as far as is possible until the joints resume their normal condition.

Infection of the Pelvic Joints.—Of the special diseases which may be encountered in the pelvic articulations undoubtedly the most common are the infectious processes. Torbett has concisely expressed the etiology of infection of joints, whether in the pelvis or elsewhere, when he states that "infectious arthritis is caused by the imperfect drainage of some mucous membrane of the body, by means of which bacteria and their toxins are retained and absorbed into the circulation and deposited in the joints." The gonococcus, pneumococcus, streptococcus, and staphylococcus are mainly responsible for these infected joints, and the spread of the poison in most of the pyemic cases takes place through the lymphatics. There must also be mentioned the traumatic origin—the possibility of a pyogenic infection of the pelvic joints from wounds, such as uncleanly tears of the cervix and perineum. Strange as it may seem at first sight, the tuberculous infections of the pelvic articulations are less frequently encountered than the non-tuberculous The infection may be a polyarticular process, or it may be confined entirely to but one of the joints. It may be acute or chronic, and serous, seropurulent, or purulent. It is now well known that puerperal sepsis and chronic inflammation of the uterus and its adnexa, whether demonstrably gonorrheal or not, may originate a secondary pelvic joint inflammation, and this infection is often due to the presence of the toxins produced by the bacteria and not to the bacteria themselves. In support of this statement reference may be made to McClure, who states that painful swellings of joints occur after injections of sterile sera, as part of the clinical syndrome known as "serum disease," these swellings being due to toxic influences working at a distance rather than to bacterial invasion of the articular structures. It is interesting to note that the arthritis which develops in the course of the infectious diseases varies from that of acute rheumatism by its non-tendency to shift from joint to joint.

The pathology of these pelvic joint infections is noteworthy. Generally it is the synovial membrane which is chiefly affected, and though bony involvement by extension may occur, it is not the rule. In the purulent cases there occurs a suppuration of the synovial membrane, which loses its epithelium; and in severe cases granulation tissue is formed, followed by fibrous degeneration or even necrosis of the cartilage, when damage to the edges of the bones ensues with destruction or grave injury of the ligaments. The relaxation which results may eventuate in partial luxation and ultimately in ankylosis of the affected joint.

The symptoms vary according to the grade of inflammation and character of the infection. They may be those of a simple synovitis or those of a severe suppurative process. The pain is usually intense, constant, worse at night, and either localized in the affected joint or referred to the legs and feet because of irritation of the adjacent nerve-trunks. If it be the sacroiliac joints that are affected these may become so swollen and enlarged as to be readily palpated or even visible. With non-tuberculous infections there is always present an infiltration of tissues, and there can occasionally be elicited a sense of fluctuation over the swollen area. Almost invariably there will be some limitation of the active spinal motions. The patient cannot bend forward the trunk when the knees are straight. Kernig's test for sciatica—inability to raise the extended leg of the affected side, passively or actively—may also very appropriately be called the sacroiliac-joint test. Moreover, there will be noted a restriction of the lateral bending of the body, and if the condition is very acute a long step in walking becomes impossible because of a spasm of the hamstring muscles, which is a very common symptom of sacroiliac joint disease of any origin. The skin over the affected joint is red and hot; the body temperature is high; the pulse is rapid; there is a marked leucocytosis in the early stage of the disease, and an increase in the percentage of hemoglobin. Finally, aspiration of the joint-contents will generally reveal the presence of the causative germ.

Treatment of pelvic joint infection: In milder cases of simple infectious synovitis fixaton and compression, with hot or cold applications, or the use of dry heat, will be all that is necessary. Suppuration requires early incision with free opening of the joint, which should be washed out and drained. It is well, in addition, to neutralize the bacteria and their toxins by the judicious use of the *x*-rays; while active or passive hyperemia in the milder cases will insure the aid of the leucocytes and antibodies of the blood.

Injuries of the Joints During and After Symphyscotomy.—In a certain small percentage of women who have undergone the operation of symphyscotomy, more or less permanent disability at the symphysis pubes has been noted. The design of the symphysis, according to Walcher, is to form with the sacroiliac joint an elastic, spongy connection between the thighs and vertebral columns. Ths is so constructed that the haunch-bones and sacrum do not move in one axis, but the pelvic planes, converging from behind forward, form two cooperating axes, which for the execution of a movement require a sliding of the haunch-bones at the symphysis. If the symphysis be ankylosed the movement of the sacroiliac joint is lost, and the jar in walking is directly transferred to the spine; while an unduly loosened symphysis permits too free movement at the sacroiliac synchondroses and destroys the stability of the pelvic girdle. Occasionally, during the instrumental delivery of the child subsequent to the symphyscotomy too great separation at the symphysis has occurred with resultant strain or even partial luxation at the posterior syn-

chondroses. These conditions are to be treated as ordinary strains and relaxation in the manner already laid down.

Malignant Disease of the Pelvic Joints. In order to complete this brief study of non-tuberculous affections of the pelvic joints mention should be made of the fact that malignant disease may invade these articulations. Inasmuch as the pelvic organs are frequently the seat of neoplasmata, the possibility of the extension of such processes to the bones and joints of the pelvis must be borne in mind.

A PRELIMINARY REPORT ON A NEW ANTISERUM FOR CANCER.*

(From The Huntington Cancer Research Institute, Cornell University, New York City.)

By WILLIAM N. BERKELEY, M.D., and S. P. BEEBE, M.D., NEW YORK.

It has long been the opinion of thoughtful students of the subject that local treatments for cancer, however necessary as makeshifts, have been based on a misconception. It is quite possible, for example, that *x*-rays or the fulguration treatment may benefit a superficial cancer at its point of origin, but the danger of such growths lies largely in their spread to distant and inaccessible vital organs, where local treatment is impossible.

We believe it therefore axiomatic that a scientific remedy for cancer shall be one soluble in the blood, transmissible by the blood and lymph currents to all parts of the body, and possessed of a selective affinity for the cells of the tumor to be destroyed.

Such a remedy may quite conceivably be a chemical substance existing in the outside world, and by happy accident discovered to have the desired properties. It is along this line that Wassermann[1] appears to have made his remarkable discovery of the effects of an eosin-selenium compound upon the cancers of mice.

Again, the remedy may be a physiological antibody, developed in an alien species by successive injections of a cancer extract. This is the line of research along which the work at the Huntington Cancer Research Institute has been conducted.

The proposition of an antibody is not a new one. The success of diphtheria antitoxin foreshadowed it. The credit for first actual suggestion of it belongs to von Dungern,[2] though many experiments by him and his pupils, and a host of other workers in all parts of the world in the next few years appear to have been quite fruitless.

The success of S. P. Beebe's thyroid cytotoxin in 1906[3] brought the cancer proposition still nearer solution, and the labors of Eugene Hodenpyl[4] for the two years prior to his death in 1909 strongly suggested the existence in a cancerous subject of a body having many of the properties in question. The problem has remained to produce the antibody in clinical quantities.

The range of the experiments at the institute has been wide. We have used various animals, many different tumors, a large variety of biochemical products (singly and in combination) as injections, and have also experimented upon dosage within wide limits. To give the work a more authoritative character, human neoplasms exclusively have been employed—a procedure which has added interest to the investigation, but has greatly increased its difficulty.

The present method of preparing the cancer extract is extremely circumstantial, requiring large special experience and a great deal of time. Many important details remain to be worked out. This part of the subject will be written up exhaustively at a later date. What has so far been accomplished may be stated briefly, as follows:

1. By successive injections of a specific human cancer extract (the cancer being partially removed by operation) into an alien mammalian species it appears that a serum may be developed which, when injected intramuscularly, or better, intravenously, in increasing doses into the original host, is followed by rapid regression and disappearance of the remains of the tumor. This cannot be done with a normal alien serum. It is hard to explain the phenomenon except as a cytolysis of the tumor cells.

2. There is a strictly quantitative relation between the amount of serum used and the amount of tumor which may be made to disappear.

3. No ill effects have been so far observed from the injections of the serum (16 cases), except local swelling and the anaphylactic fever and vasomotor disturbances noted after giving an equal amount of normal foreign serum.

4. The relation of one antiserum ("stock serum") to histologically different cancers is variable and full of surprises. It will take years of labor to determine all the curious chemical affinities that may be involved.

5. Present clinical results are briefly as follows: Sixteen cases of malignant disease in all stages of advancement have been treated in the last nine months by surgical friends interested in the research. A microscopical diagnosis was made in all but three cases. Fifteen were cancer and one was sarcoma. Nine received stock serum, one received autogenous serum after a secondary operation, six received autogenous serum after a primary operation. Of the nine patients receiving stock serum two were moribund when first seen, and died quite uninfluenced by the injections; another, having cancer of the esophagus, was remarkably benefited for several weeks; one, with an immense cancer of the tonsil, was somewhat benefited temporarily. One very extensive primary cancer of the bladder has not been recently heard from, but was probably not benefited. Of two im-

*Read before the Section on Gynecology, New York Academy of Medicine, Feb. 23, 1912.

mense cancers of the stomach, one was entirely unaffected, one slightly improved. One patient (breast case), after two months of injections, is nearly well and in excellent general condition. Another case (uterine cancer recurrent in the bladder) recovered promptly and has remained entirely well for four months. One far advanced breast case receiving a small amount of autogenous serum after a secondary operation, was greatly improved, but subsequently died of intercurrent acute disease. Of the patients receiving autogenous serum after a primary operation one is still under treatment, greatly improved; the others have had no recurrence within a period ranging from three to six months.

To the above conclusions some practical comments must be added.

The present impression of the writers is that autogenous serum is much more effective than stock serum. It is believed that the great field of usefulness of the new serum will be to prevent the recurrence of malignant tumors removable in the early stages by operation.

There is no indication from present experience that large inoperable cancers and sarcomas will be amenable to the serum treatment. Treatment, to be effective, must be early if there is to be any reasonable quantitative relation between tumor and antibody.

It is fully recognized that the cases so far successfully treated are too few in number to justify sweeping claims for the future. The object of this first report is to state the facts that have been proved, to answer numerous questions, and to clear up many misapprehensions in regard to the serum treatment.

For helpful assistance in the work heartfelt thanks must be expressed to many professional friends and acquaintances, particularly to Dr. Geo. W. Roberts, Dr. Frank R. Oastler, Dr. Francis Foerster, Dr. Norbert Stadtmüller, Dr. F. L. Taylor, Dr. Martin Rehling, Dr. Franz Torek, Dr. Henry M. Silver, Dr. H. Fischer, Dr. George H. Semken, Dr. Geo. D. Stewart, Dr. John Aspell, Dr. Dougal Bissell, Dr. Edward W. Pinkham, Dr. R. M. Rawls, Dr. B. McGeorge Dear (resident interne, German Hospital), and Dr. Wm. M. Ford. Special thanks are due to Dr. Ford, whose interest has been untiring, and whose suggestions have repeatedly proved to be of great value.

CLINICAL ACCOUNTS OF THIRTEEN CASES TREATED WITH A NEW ANTISERUM FOR MALIGNANT DISEASE.*

BY WM. M. FORD, M. D.,

NEW YORK.

IN presenting these cases it is my purpose to offer for your consideration some clinical observations that have been made while using an antiserum for cancer prepared by Dr. Berkeley.

In all, I have administered this remedy in thirteen cases, which for convenience of description are spoken of by their numbers. Of these, Cases I and II (cancer of the breast and stomach respectively) were *in extremis* before the remedy was administered and died within a few days after the initial injection. Three patients took the serum irregularly, and of these two expressed themselves as having been benefited, Cases III and IV (cancer of the stomach and throat, respectively), the third Case V (a cancer of the bladder) seemed to be of the contrary opinion. Nothing definite, however, could be determined, and for that reason the entire group will be dismissed from further consideration.

CASE VI, a patient upon whom a large amount of serum was expended without benefit, after a clinical diagnosis of cancer of the bladder had been made by a most capable genitourinary surgeon, proved after operation to be non-malignant.

CASE VII, in which only a clinical diagnosis of carcinoma of the esophagus was made, after apparent improvement for a short time ultimately succumbed.

CASES VIII, IX, and X each had autogenous injections after primary operation. As yet none has shown evidence of recurrence, but the operations are of such recent date (three to six months) that this fact indicates nothing.

There remain to be reported upon Cases XI, XII, and XIII, and the histories of these are presented somewhat in detail.

CASE XI.—Miss E. S., age 42 years, single, native of the United States. A diagnosis of pulmonary tuberculosis had been made several years previously, but never substantiated. The woman was operated upon on November 5, 1908, for carcinoma of the left breast, as verified by Dr. Harlow Brooks. On September 13, 1910, patient presented herself on account of pain and thickening of the tissue surrounding the scar resulting from the operation. Tissue removed from this area proved to be recurrent carcinoma. From February, 1911, until May 2, 1911, the patient was given minute doses (0.5 to 1 c.c.) of stock serum subcutaneously, at relatively long intervals, by Dr. Berkeley, who at this time discovered a mass in the right breast and referred the patient to me again for consultation. I found that the right breast, which was quite small, consisted almost entirely of what subsequently proved to be carcinoma. The axillary glands on this side were markedly enlarged. One mass was distinctly palpable; about the size of a walnut. On the left side the disease had extended in the lymphatics of the skin, as low as the umbilicus and as high as the clavicle. The intervening triangle was studded with a vast number of pea-like masses, distributed along the course of the lymphatics. In addition there were numerous areas of wart-like growths on the site formerly occupied by the breast, having a combined area approximately the size of a silver dollar. The patient was greatly emaciated, had a persistent cough, and suffered continually from pain at the site of the old scar to such an extent that about a grain of morphine was administered daily. In spite of the patient's condition a rapid amputation of the remaining breast was done on May 2, and an autogenous serum was prepared. I felt the patient was fortunate to survive the 15-minute operation, and having at that time no particular confidence in the action of the serum, I made a prognosis of about two months upon the life of the patient. The autogenous serum was injected subcutaneously and intravenously, between

*Read before the Section on Gynecology, New York Academy of Medicine, Feb. 23, 1912.

June 16 and July 31, 1911. The wart-like carcinomas shrank materially during this period and the purple pea-like areas of induration diminished distinctly, many of them entirely disappearing. The axillary glands on the right side resolved to such a degree that they were little more than palpable. The morphia was completely withdrawn and to the time of the patient's death was never resumed. The patient's weight remained stationary during this period, and she was sent away to the country to recuperate. On September 8 she returned suffering from a severe bronchitis, and it was not until September 29 that it was thought advisable to begin the administration of stock serum. From this time on the patient slowly but persistently lost weight. Her left pleural cavity filled with serum from time to time and required aspiration about every two weeks. The fluid removed, however, was almost perfectly clear amber, and free from any suggestion of blood. As our supply of serum at this time was scarcely adequate the injections were given only about once in ten days. The last week in January, 1912, the patient suddenly ran a temperature of 103°, her respirations rose to 48, and within forty-eight hours she died. No autopsy was obtainable. An inspection of the breast at this time disclosed an utter absence of the cauliflower growths, and by passing the hand over the skin of the left chest, but a few small shot-like masses could be palpated. Not more than two or three were discernible to the eye.

Case XII.—Miss M. S., age 53, single, U. S., was admitted to the Woman's Hospital on November 22, 1911. Had always enjoyed good health until about thirteen years ago, when she detected a lump in her left breast. Was operated upon in the Mount Vernon Hospital, March 10, 1899. Although apparently a radical operation was done, the patient states that the pathological report rendered at that time was to the effect that the growth was non-malignant. In September, 1910, eleven years after, she noticed a "red spot" the size of a quarter, near the old scar. In September, 1911, ulceration began and in November the patient applied for relief to Dr. Pierson, under whose care she remained until referred to me.

Examination.—The ulcer on the site of the old scar measured 2⅝ by 2 inches, with irregular, indurated, and precipitous borders and was covered with necrotic tissue. Over the cartilage of the third rib, near the sternum, and just without the margin of the ulcer, was a tumor the size of a walnut, intimately adherent to the underlying hard structures and of a consistency suggesting calcareous changes. At the lower margin of the ulcer was a similar tumor about the size of a hazel nut, and to the outer side a third of nearly the same size. The first two were of a deep purple color, and seemed about to necrose on the surface. The cervical glands were slightly enlarged but soft. The upper outer quadrant of the right breast appeared somewhat hypertrophied, and the axillary glands, while slightly enlarged, were not tender. Between November 23 and December 12 she received two injections weekly of the stock serum, and on the latter date the greatest dimensions of the ulcer were 1½ by 1⅞ inches. Treatment was continued semiweekly until on January 22, 1912, the ulcer had entirely healed. On January 30 a slight ulceration appeared on the surface of the larger of the two tumors. Since that time it has scabbed over and all the tumors have materially diminished in size. The patient has slowly gained in weight. She is still under treatment in the hope that the two remaining evidences of malignancy may be eradicated. It is important to note that on January 8 a specimen was removed from the intermediate of the two tumors, which proved to be unquestionably carcinoma.

Case XIII.—Mrs. C. was admitted to the Woman's Hospital on August 10, 1911. Age, 52 years. Menstruation ceased seven years previously. Married at eighteen years of age. Contracted a disease from her husband which resulted in cord sclerosis; this has remained stationary for the past thirty years. For the past year and a half patient has had severe uterine hemorrhages, usually lasting twenty-four hours and followed by a continual bloody discharge which obtained until the occurrence of the next hemorrhage. During the past year she has lost twenty pounds. Lately has had incontinence and painful micturition.

The urine was pale, straw-colored acid; specific gravity, 1012; sugar, negative; albumin, faint trace; sediment of blood and epithelial cells. Local and constitutional measures for the relief of vesical irritation had been without avail, and the patient was suffering almost continually from bladder tenesmus. The Wassermann reaction was negative. A clinical diagnosis of cancer of the uterus having been made, on August 30, panhysterectomy was done in the hope of perhaps improving her general condition. On September 7, while she had made a good recovery from the operation, the condition of her bladder was not improved, and the desire for frequent micturition seemed, if anything, increased. The patient was referred to the cystoscopist of the hospital, Dr. A. T. Osgood, who reported: "Base of bladder shows extensive bullous edema with one edematous, bluish mass, evidently in the grip of the internal vesical sphincter. Base of bladder, per vaginam, feels thick. Diagnosis, carcinoma of floor of bladder." Upon the strength of this opinion, 5 c.c. of stock serum prepared from a breast cancer was injected subcutaneously September 20, rather with the idea of observing its effect than in the hope of effecting much relief. To our surprise the relief was almost immediate. Thus encouraged, on September 23 the dose was repeated, and on September 25, 10 c.c. was injected intravenously. Following each injection the patient complained of slight faintness and severe headache. On October 3, the patient having been relieved from all symptoms from about the time of her first injection, she was referred to the cystoscopist for a second examination. All information as to the administration of the serum was purposely withheld until his observations had been recorded. I quote his second report, in part: "Bullous edema has disappeared. Internal vesical sphincter is nearly of normal appearance. Base of bladder, per vaginam, no longer feels thickened. Bladder shows moderate subacute cystitis and vesical outlet shows a slight degree of edema and redness. The case is, therefore, to be looked upon as not carcinoma of the bladder, as stated previously." The pathological report from Dr. Ira Van Gieson verified the clinical diagnosis of carcinoma of the uterus. The patient left the hospital on October 12, 1911, feeling quite restored to good health. I saw her at the end of February, 1912, when she reported a gain in weight of ten pounds, and voluntarily stated that her general health was better than it had been in years.

It gives me pleasure at this time to express my thanks to the gentlemen who have assisted me in this work and in particular to Dr. Austin Flint, Jr., for placing at my disposal certain cases in the Woman's Hospital.

BERIBERI;*

WITH A SUGGESTION FOR GOVERNMENTAL AID IN ITS ERADICATION.

By VICTOR G. HEISER, M.D.,

MANILA, P. I.

SURGEON, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE

The various phases of the beriberi question have been so extensively reported upon during the past few years that it is with considerable hesitation that I present any remarks on this subject to an audience that is so well versed in the recent developments in connection with this disease. Taking it for granted that there is now sufficient proof available that beriberi in the Orient occurs most frequently among those whose staple article of diet is polished rice, it was thought that perhaps it might be of interest to present some of the steps we have taken and the experiences we have had in the Philippines in attempting to bring about the general use of unpolished, or undermilled rice.

In the first place, in order that there might be a standard as to what constituted polished or unpolished, or overmilled or undermilled rice, Dr. Aron of the College of Medicine and Surgery of the University of the Philippines undertook a series of experiments on chickens, as a result of which he came to the conclusion that any rice which contained .4 of 1 per cent. of phosphorus pentoxide or more might be regarded as undermilled rice, and therefore safe as a staple article of diet, and any rice that contained less than this percentage of phosphorus pentoxide should be regarded as overmilled rice, and therefore unsafe as a staple article of diet. From recent experiments it appears that potassium or other substances found on the outer portion of the rice grain might be used equally well as an index of the degree of polishing.

In spite of the remarkable success in reducing the number of beriberi cases that occurred in the military and civil establishments in the Philippines soon after the use of undermilled rice was made compulsory, it early became apparent that only by the most urgent insistence could its continuous use in even such circles be brought about. Many of the more ignorant believed that on account of the darker color of the unpolished rice the government was trying to force a cheap and inferior article upon them. Commissary officers, prison wardens, captains of vessels, and others directly charged with carrying out the orders to use undermilled rice were constantly besieged with complaints. It was but natural that they should take the course of least resistance and recommend that its use be discontinued. During the early period of the introduction of unpolished rice there was undoubtedly some cause for complaint owing to the fact that the rice mills were slow in adjusting their process of manufacture so as to produce rice that was well cleaned and only sufficiently polished so that the P_2O_5 did not fall below .4 of 1 per cent. These difficulties were gradually overcome, but in spite of that much prejudice still remains. Considerable effort has been made in the way of education. Public lectures have been given, instruction in the schools has been undertaken, and the daily and weekly newspapers frequently contain articles upon the cause of the disease and how to prevent it. Since it has been so difficult to bring about the use of unpolished rice among persons for whom the Government furnishes the rations and whom it is possible to reach so directly by education, and even enforce its use if need be, it must be apparent that at best the adoption of unpolished rice by the masses would necessarily be slow.

Legal opinion is quite favorable to the idea that, under the provisions of the food laws in force in the Philippines, the sale of polished rice might be prohibited. Whether it would be advisable to attack the problem from that standpoint is, however, very questionable. The enforcement of such a law would be almost sure to incur the passive opposition of even those persons who use the European diet. To prevent such persons from purchasing polished rice would not be of any assistance whatever in reducing beriberi, and at the same time the sanitarian would deprive himself of the very aid of those members of the community upon whom he must necessarily depend to assist him in disseminating the information among the masses that polished rice causes beriberi among those who use it as a staple article of diet.

At first it was thought that the most effective way of insuring the use of unpolished rice would be to prohibit the manufacture of polished rice, but that procedure is also open to the objection that it would prevent the use of polished rice among those whom it does not harm. In addition, such great opposition would no doubt be made by the owners of rice mills that legislation might be impossible to secure.

Another plan suggested was the imposition of a license fee upon both retail and wholesale dealers who sell polished rice and to make this fee sufficiently large so that the cost of polished rice would be beyond the reach of the masses; but this method would probably require an enormous amount of supervision for its successful enforcement. Controlling such sales in remote regions would be exceptionally difficult. A number of other expedients were suggested, but all of them had such serious objections that they had to be abandoned.

The conclusion ultimately reached was that the object sought could probably be most successfully attained by placing a tax of say five centavos (approximately five cents Mexican) per kilo upon every kilo of rice that is polished and no tax upon unpolished rice. The standard by which a rice is to be judged should be definitely fixed by law and can be well based upon the amount of phosphorus pentoxide which it contains; in other words, a rice that contained .4 of 1 per cent. of phosphorus pentoxide or more would be regarded as an unpolished rice, and rice that contained less would be regarded as polished rice. Such a standard would be very simple of application, and would not be likely to cause serious misunderstandings. It would also have the additional advantage of providing definite testimony with which to go before the courts in the event that judicial action became necessary. In view of the fact that the quantity of rice consumed by those who use the European diet is merely nominal, such a tax placed upon polished rice would scarcely be felt by them, and would

*Read at the second Biennial Congress of the Far Eastern Association of Tropical Medicine at Hongkong, Jan. 22, 1912.

not be likely to result in any opposition, whereas the masses would almost be compelled to purchase the untaxed rice. Such a law would cause no hardship, and at the same time would provide a final and conclusive test of the correctness or the incorrectness of the predominating view with regard to the etiology of beriberi. It is also capable of being effectively and economically enforced.

It was the intention to place such a law in force in the Philippine Islands during the present year, but owing to the shortage of the rice crop and the general disturbance of the market which resulted therefrom it has not been deemed expedient to attempt it yet.

This plan seems so feasible, however, that the writer desires to recommend to the association that a suitable resolution be drafted for the purpose of bringing it to the attention of the governments in the Orient. It is believed that such a measure would be entirely practicable and would be almost sure to result in an enormous reduction in the beriberi mortality and morbidity in a few years' time, and it is not too much to hope that the disease may be entirely eradicated in the near future. The association would be complying with its highest ideals in pointing the way to health and happiness instead of permitting the unwary to tread the path of disease and death. If such a result as this could be brought about it would add another great triumph to modern prophylactic medicine.

SCHOOLS FOR MIDWIVES.*

By IRA S. WILE, M.S., M.D.,

NEW YORK.

It is desirable to strengthen the position of those who do not regard the elimination of the midwives as the only solution of the problem. We must recognize that the midwife does present a problem that has received too little attention in this country. The New York Academy of Medicine in 1906, the New York State Medical Society, the Committee on Midwives of the Chicago Medical Society in 1908, the Erie County Medical Society, and a Conference on the Prevention of Blindness held in New York, 1911, are a few of the organizations that have gone on record as favoring "state legislation which shall provide for the training, registration, regulation, and control of women engaged in the practice of midwifery." From a questionaire sent to the State Boards of Health State provision for the training of midwives is favored by nineteen States, including Arizona, Connecticut, Florida, Idaho, Delaware, Illinois, Indiana, Louisiana, Minnesota, Mississippi, Montana, Pennsylvania, North Carolina, North Dakota, Rhode Island, South Dakota, Utah, Virginia, West Virginia, and Wisconsin, Maine, Nebraska, and Ohio oppose this, while eighteen states sent no answer. Massachusetts favors regulation or elimination. The balance of opinion apparently is gravitating toward education and regulation.

Much is said about the ignorance and incompetence of the midwife and the existence of this condition may not be denied. But it is manifestly unfair to criticise the lack of an educational standard which has never been established. When nurses were of the Sairy Gamp type elimination was not the cure. When apprenticeship was the open sesame to the practice of medicine and the average of competence was not high elimination was not the cure. Education training, regulation, and control solved these problems just as they will solve the midwife problem. Establish an educational standard, provide sufficient facilities for giving the adequate training, secure the legislation essential to provide supervision and control and then raise the standard of the midwife so that no further fault may be found. Let us be fair to the midwives and to their patients. Let there be an evolution of this class of public servants and not a hasty attempt to check their possible development.

When so much stress is placed upon the ignorance of the midwives it behooves us to remember that eleven States still have no provision in laws for the preliminary education of physicians. Twenty-eight States demand an educational equivalent of four years of the high school or higher. Obstetric training in the medical colleges is recognized as inadequate, but there is no voice raised to eliminate the doctor from the practice of midwifery. Dr. Hirst is at present circularizing the State Boards of Health to establish a standard of obstetrical experience for candidates for licensure and the standard he suggests is the personal delivery of at least six women. In New York City the midwife is required to have had the personal care of twenty women before a permit is granted to her. The irregular practitioner of medicine is still permitted to be an obstetrician with an experience that is inferior to that possessed by more than half of the midwives. Let us be fair to the midwife and if she is below the ideal we have for her, though we have never crystallized that ideal into law, let us give her the opportunity to rise and educate herself under proper supervision. Then as a further protection to society let us arrange for the necessary supervision and control.

Dr. Van Peyma, professor of obstetrics at the University of Buffalo, who was active in securing the midwife law for Erie County, states: "The diagnostic ability of midwives is generally good and in the case of many remarkably excellent. In this respect the average midwife is fully the equal of the average physician. If we look at the matter fairly and broadly, considering the facts of asepsis, diagnosis, and general management on the one hand and the question of time involved, artificial deliveries, lacerations, compensation, etc., on the other, the writer is not inclined to believe that the average woman on the East Side, now employing a midwife, would on the whole receive better attention and results if she were to employ physicians obtainable for double the fees paid to midwives—to say nothing of the duties of nurse to mother and child, now furnished by the midwife." These remarks were based upon conditions in Buffalo, where one-half of the births are reported by midwives and where the average fee paid to the midwife is $5.

Midwives will be a part of our social system as long as immigration exists and until the newcomers of to-day are thoroughly Americanized. The Mexicans in Arizona, the Americans in North Carolina; the Italians, Swedes, and Syrians in Massachusetts; the Hungarians, Bohemians, Germans, Italians, Slavs, Poles, Swedes, and Finns in Ohio, and the negroes in Missouri make use of midwives, and along with the Russians and Austrians give some idea as to the national basis of the problem and the degree of distribution that must be re-

*Read before the American Association for the Study and Prevention of Infant Mortality, Chicago, Ill., November 18, 1911.

quired of any educational reforms. That the difficulties arising from the midwife problem are not centered entirely in the city is evident from the fact that in Nebraska, Oregon, Utah, and West Virginia, for example, the bulk of the midwives are busy in rural communities.

As Dr. Baker has said, nobody knows how many midwives there are in this country. The total number registered does not serve as an index of the total number at work. Connecticut has registered 127; Illinois, 1,396; Indiana, 175; Iowa, 40; Massachusetts, 150; Mississippi, 203; Ohio, 643; Pennsylvania, 433; Rhode Island, 15; Utah, 326, and Virginia, 200. The figures presented, representing official State information, show only 3,708 midwives and the 28 cities reported by Dr. Baker estimate the number of midwives as 3,360. In 21 cities 72,966 births were reported by midwives annually. The percentage of the total number of births reported by midwives varied from 5 to 53 in different cities.

Massachusetts presents the anomalous situation of not recognizing the midwives as legal practitioners, but accepting their signatures on notifications of birth. This is a false position. Educate the midwife and give her recognition. Increase her self-respect and arouse her pride in her work and its results. Give caste and dignity to midwifery and a more intelligent type of woman will enter the profession. Place the full measure of responsibility upon the midwives and treat them as human beings endeavoring to fill a need expressed by the communities in which they live. Remove from them the cloud of suspicion that now exists. Establish their legal status upon an educational standard that may be attained in institutions under supervision and control by the proper authorities. If midwives are ignorant it is because we have permitted them to develop thus. We are to blame and they are not. The criminal aspects of the midwife problem will be helped in so far as a more enlightened and trained set of midwives may be held to stricter account in the matter of licensure and will have more reason for adhering to the highest moral and legal standards. From this point of view the skirts of the medical profession are not entirely clean nor can we hope to eliminate the abortionist by education or law.

That the training and education of midwives will lessen the mortality of mothers has already been demonstrated. For the fifteen years previous to the passage of the Midwives Act in England in 1902, the death rate from puerperal sepsis varied from 109 to 202 per million females living; in 1903 the rate dropped to 97 per million, and in 1907 was down to 87 per million. In Italy during 1887, when the government assumed control and gave governmental education, the death rate from puerperal fever was 87 per million females living; in 1890 it fell to 56 and in 1902 fell to 32 per million. In New York City the reported cases of death from puerperal sepsis occur more frequently in the practice of physicians than in that of the midwives. Restricting the practice of the midwives to the delivery of normal cases requires a knowledge of diagnosis. The fact that 80 per cent. of the midwives of New York City present a diploma from some sort of school of midwifery indicates a desire on the part of the majority to acquire an adequate training before entering upon this field of endeavor. A midwife should be able to read and write the language of her native land at least, preferably, of course, English, that she may be able to make proper returns to the authorities and to read the official regulations. She should then have a course of training covering at least six months and involving practical study of the subject as the basis of the theoretical training. At least twenty cases should be under her personal care, although with effective supervision that the rules of asepsis may be thoroughly ingrained. The graduates of schools of midwifery should be under the control of local or municipal authorities and should receive training in connection with hospitals and out-patient departments. The educational standards might better be established by the State departments so that uniform standards might exist throughout the State. The enforcement of these standards could be left to the various local departments of health. By this means the numerous schools of midwifery that are at present existent, without recognition, would come under adequate control and their work would be supervised and be placed upon a higher plane of efficiency.

Let us train, supervise, and control the midwives and give them an opportunity to take a reputable position in their work, guaranteeing them protection in proportion to the protection that they give to their patients, the mothers who need and demand them.

230 West Ninty-seventh Street.

THE TREATMENT OF ECZEMA RUBRUM OF THE LOWER EXTREMITIES.

By PAUL E. BECHET, M.D.,

NEW YORK.

CLINICAL ASSISTANT IN DERMATOLOGY, NEW YORK SKIN AND CANCER HOSPITAL, ASSISTANT DERMATOLOGIST, DEMILT DISPENSARY

My excuse for the presentation of this very trite subject lies in the obstinacy of the condition and its severe subjective symptoms. The itching and burning is always severe, and at times patients suffer almost untold agony, which even continues in their sleep. Relief is sought by scratching and rubbing, which causes bleeding and increased inflammation and at times severe secondary infection. There is also in certain cases with varices considerable pain due to venous stasis, which in these particular cases is a strong contributing factor in the production of the eczema. Aside from the subjective symptoms, the raw, red, weeping surface, occasionally more or less covered with large yellowish scales, the exuding sticky serum adhering to the dressings, the blood stained bedclothes, etc., are anything but agreeable to the unfortunate patient. The question of relief is therefore far more important than any abstruse discussion as to etiology of the condition. Given such a case, what can best be done?

First, we should inquire minutely into the patient's physical status, keeping a carefully written clinical record. We will find a majority of these patients show an increase in body weight, that the intake of food is greater than the output, that they may indulge in alcohol more or less excessively, that they either live very sedentary lives, or have positions which require continuous standing, that their intestinal tract is clogged, and their urine shows an excessive amount of solids and indoxyl, and that there are frequently varices of the superficial veins. The internal treatment of eczema rubrum is therefore of great importance. Of the large number of cases I have seen, I do not know of a single patient who

showed no indication for medication or whose health had not improved to a great extent after taking the medicaments prescribed, whether these were tonic, laxative, diuretic, stomachic, alkaline, etc. In other words, one should not have a few favorite formulas, but be guided entirely by the clinical findings of the particular case. The intake of meats and sweets should be greatly limited, the amount of limitation to be guided by the urinary findings and the condition of the patient. Alcohol in any form is absolutely to be interdicted. The bowels must move daily. The patient must have a certain amount of fresh air. He should have at least eight hours sleep. Locally, the first indication would be the surgical removal of any varices if present. This could be done at almost any stage of the eruption, as the enlarged veins are most frequently to be found above the eczematous area. Should this not happen to be the case, it would be best to relieve the eczema and then treat the enlarged veins surgically, thereby reducing greatly any chance of recurrence of the eruption.

The most important single factor in the local treatment of eczema rubrum of the legs is undoubtedly the solid rubber bandage, as introduced and advocated by Dr. L. Duncan Bulkley. I have seen the truly splendid results achieved by its use, both in his and my practice, and in my clinics. The bandage is made of very thin rubber, capable of a great degree of stretching. It is about three inches wide and about five yards long; should it be necessary to carry it to the thigh, a longer bandage is required. The method of applying the bandage is simple. No matter how small the area of eruption, it is best to apply it from the toes to the knee, overlapping it about one-third of its width. The bandage should never be reversed, the heel must be left free. With only a slight amount of care, an even amount of pressure can be maintained and the comfort of the bandage elicited by having the patient stand and walk about. If at any time it proves uncomfortable it should be removed and readjusted. The bandage is not to be applied directly to the diseased parts. I use pieces of ordinary surgical lint, cut so that the borders just meet together, surrounding the leg with one thickness of cloth without overlapping. The woolly side of the lint is then covered thickly with the salve to be used and applied snugly to the diseased area. The rubber bandage is then applied. At night the bandage and dressings are removed preferably after the patient is entirely ready for bed. The rubber bandage is washed in a diluted solution of phenol (one dram to a pint) drawn through a dry towel, draped over the back of a chair, and left to dry overnight. The leg, with the accumulated secretions of the day should be washed off with some weak antiseptic solution, preferably phenol, because of its marked antipruritic properties. A large piece of cotton should be used as a sponge. The leg is then gently dried with absorbent cotton, causing as little irritation as possible. An astringent cooling lotion is then applied, twice, at a fifteen-minute interval, in order to allow the first application time to dry, before the second is put on. If during the night there should be any itching, a piece of cloth wet with the lotion should be applied. In the morning, before arising, the leg is dressed and the rubber bandage applied as previously described. Should any dressings be used during the night, and these are adherent, they should not be forcibly torn off, but should first be moistened with a little olive oil. If this is done they can be removed without force.

The advisability of using the rubber bandage in the very acute stages is questioned by some, yet I have used it time and again in my clinic with nothing but good results. The exudation of serum is controlled in a remarkably short time. There is no difficulty in training patients to use the bandage rightly; with a little patience and several demonstrations, they will carry out all details minutely. The benefit derived from the use of the bandage is a further incentive to obey instructions.

40 East Forty-first Street.

MALARIA IN AN INFANT FIVE MONTHS OLD, SIMULATING VON JAKSCH ANEMIA.

By ALFRED C. HENDERSON, M.D.,

NEW YORK,

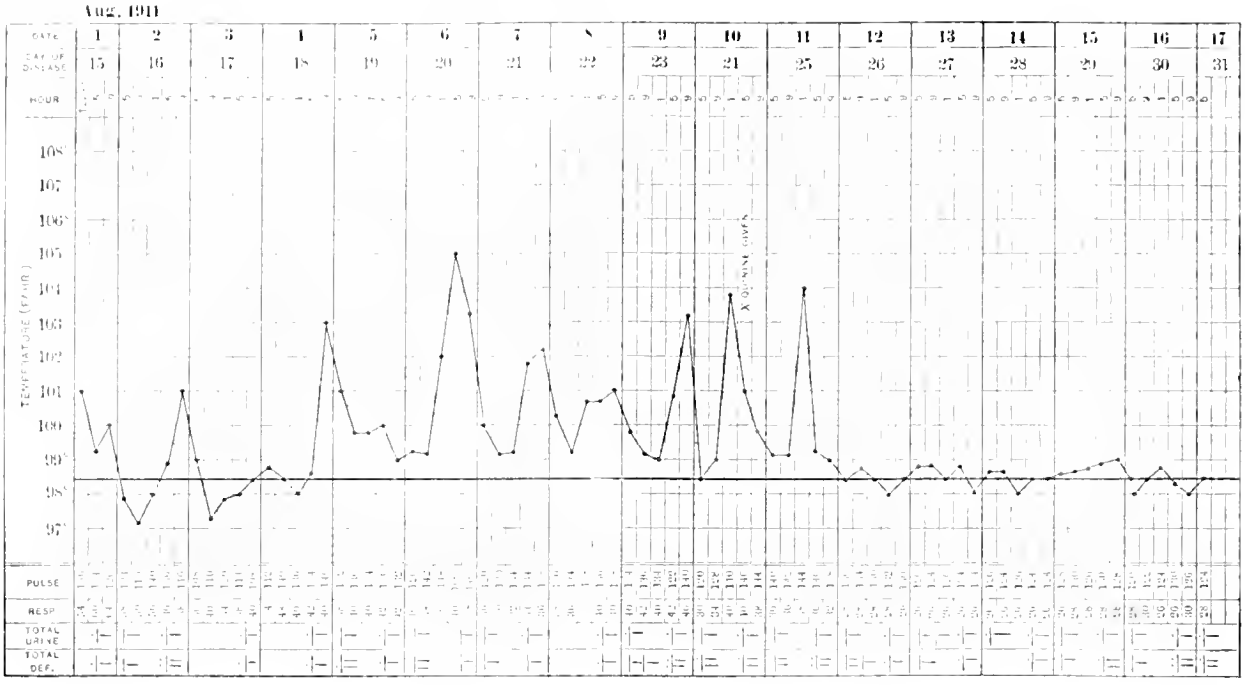
ASSISTANT VISITING PHYSICIAN, GOUVERNEUR HOSPITAL.

Malaria in infants is probably not rare; undoubtedly there are many infantile cases that are not recognized. The blood findings simulating von Jaksch anemia (pseudoleucemia of infancy) and the age of the patient are the reasons for reporting this case.

History: No history of syphilis or tuberculosis in the family. Parents and three other children living and well. The patient, a male infant, five months old, was admitted to the hospital on August 1. The mother said the child was normal at birth and labor was normal; birth weight unknown. Was breast fed, but during the three or four weeks previous to admission child was given two bottles daily containing flour and water. Child has never been out of New York City. No illness until the present, which began about three weeks ago. Mother gives the ordinary indefinite history of gastrointestinal disturbance, with slight cough. Constipation was more often noticed than diarrhea. Laxatives seemed to help at first, but during the week before admission he became weaker and the mother noticed that his color was yellowish. As he seemed to be "failing" he was brought to the hospital.

Physical examination: Male infant, fairly well nourished, but very anemic in appearance. Lies rather listlessly in bed. Head: Nothing abnormal found. Pupils normal in reaction. No jaundice. Ears negative. Mucous membranes of mouth and pharynx appear almost bloodless. Thorax: Lungs, normal resonance throughout. Heart, rapid; not enlarged; no murmurs. Abdomen: Liver not palpable. Spleen markedly enlarged; firm, not tender; extends downward to level of umbilicus and inward to within 2 inches of median line. Extremities normal. Lymph nodes: One small node palpable under right side of jaw. Skin, waxy-yellowish. Weight: 11 pounds 8 ounces, on admission. Blood: August 1, red cells, 1,036,000; white cells, 30,000; hemoglobin, 20 per cent. Differential: lymphocytes, 68 per cent.; polynuclear neutrophiles, 30 per cent.; mononuclears and transitionals, 2 per cent.; five normoblasts found while counting 500 leucocytes; no eosinophiles were found in any of the counts; no malarial organisms found.

August 5, red cells, 1,800,000; white cells, 18,600; hemoglobin, 25 per cent. Differential: lymphocytes, 72 per cent.; polynuclear neutrophiles, 24 per cent.; mononuclears and transitionals, 4 per cent.; no malarial organisms found. August 10, red cells, 1,500,000; white cells, 18,000; hemoglobin, 20 per



cent. Differential: lymphocytes, 64 per cent.; polynuclears, 33 per cent.; mononuclears and transitionals, 3 per cent.; malarial organisms numerous.

On account of the severe anemia it was thought necessary to get the child under the influence of quinine as rapidly as possible; so the bimuriate was given hypodermically, four grains daily in divided doses. As may be seen by the temperature chart, there was 104° fever the day after the quinine was begun, and then a practically normal temperature. The child made an uneventful recovery. The decrease in size of the spleen was especially noticeable; ten days after quinine was first given the spleen could hardly be palpated. The case was first diagnosed as pseudoleucemia of infancy, but the finding of malarial organisms of course indicated the correct diagnosis and treatment.

Several authorities maintain the pseudo leucemia of infancy is not a clinical entity. They hold that such cases are cases of anemia of various origins (syphilitic, rachitic, or after wasting diseases) and are mere examples of the manner of response of infants to severe anemias. In support of this it must be remembered that (1) the normal blood count of infants resembles the leucemic count of adults in the excess of the lymphocytes over the polynuclears; (2) the normal hemoglobin percentage of infants is lower than that of adults, and (3) the spleen in infants readily becomes enlarged during any severe anemia. The foregoing case is of interest in showing that the malarial organism may be the etiological factor in an anemia of this kind.

155 East Sixty-second Street.

HEREDITY, ENVIRONMENT, OR ACCIDENT?

By Walter Sands Mills, A.B., M.D.,
New York.

There is a belief that many constitutional diseases are hereditary; that is, if a number of cases of the same disease occur among a number of members of the same family the disease is either handed down directly from parents to children, or the predisposition to it is handed down. This may not be stated in ultrascientific language, but I think my meaning is sufficiently clear. Thus we know that in tracing the family history of a patient with cancer, with epilepsy, with insanity, or with one of many other conditions, we will find often that other members of the same family are or have been afflicted with the same disease. A vast number of such observations has led to the belief, therefore, that certain unknown family characteristics must be at work.

The belief was once almost universal that tuberculosis was hereditary; that is, that it was handed down directly from parent to offspring. Since the discovery of the tubercle bacillus the old belief has given way, and now the prevalent idea is that the intimate relations existing between members of the same family cause the disease to be passed from one to another by infection. Even so, some members escape, and to explain this it is said that those affected must have a predisposition to it, which seems to me to be heredity again. Within a very short time Landouzy, of Paris, has announced that he has been able to demonstrate that tuberculosis is directly transmissible from parent to offspring, through several generations of rabbits. Syphilis is surely transmitted from parent to offspring through at least two generations sometimes. This is true heredity.

With such knowledge as the above, and similar facts regarding many other diseases, it seems almost impossible to eliminate heredity altogether. Nevertheless, environment plays some part, and a very great part, in disease as in other things. For this reason the physician should not lay too great stress on heredity, but should search among all the other factors that may enter into the possibilities in looking for the cause of a given condition. I well remember when in 1896 I was taken ill with tuberculosis, and sent West; how the fact that I had lost a brother with that disease in 1894 made me think that my case must necessarily prove hopeless. Some of my distant relatives also had died of tuberculosis; it was in the family, and the outlook was gloomy. One day, while in Albuquerque, there was a celebration of some sort, with a torchlight parade and fireworks. In some way the wagon containing the fireworks in that procession caught fire. The man who drove the wagon was

a hero, for he stuck to his post and kept the frightened horses from dashing into the crowd of sightseers, where many might have been killed. But the driver himself died of his burns a few hours later. On looking up that man's family history it was found that he had had three brothers, all of whom had been burned to death. Surely no one could call burning to death an hereditary disease, or one that a family could have a predisposition to on account of heredity! This made me think. Curious as it may seem, my tuberculosis began to improve, or my mental attitude toward it, until I entirely recovered. From time to time I have collected other instances of family fatalities, or whatever they may be called, and will reproduce some here.

I. A boy twelve years old was accidentally shot and killed in Brooklyn by a playmate. The boy lived with his grandmother. Seven years before another grandson, aged twelve, living in Alabama, was killed while shooting off a toy cannon. Still a third grandson was killed in New Jersey at the age of twelve. He was hunting muskrats with some other boys, when one of his companions mistook his cap for a muskrat and shot and killed him.

II. A man, twenty-three years old, was killed by an iron bar projecting from a passing train. His father was killed by a train at the same place, eighteen years before. These accidents occurred in New Jersey.

III. A gas stove upset and burned a man in Brooklyn so badly that he died a few days later. A few years before his daughter-in-law was set on fire by the kitchen range, and died as a result. Six months later the wife of the Brooklyn man was burned to death by an oil stove.

IV. Two trainmen, brothers, were killed in the same head-on collision. This occurred in West Virginia. One brother was in the crew of one train, the other was in the crew of the other. Two other brothers had previously been killed in train accidents.

V. A little girl of ten was accidentally killed on the street in New York. A year before a brother had been killed by a fall from a window.

VI. One brother was drowned while swimming in June. The following February another brother was drowned while fishing. These accidents occurred in Long Island.

VII. A father and son were murdered at an interval of four years. The crimes were otherwise unrelated in any way.

VIII. Two young men that I knew were killed several years apart by trains. They were railroad employees. A third brother fell out of an apple tree and was killed. A fourth brother was hit by a baseball and killed.

And so on, the gruesome list might be extended indefinitely. Of course, railroad men run special risks, and there may be a family predilection for the railroad business. The three boys of twelve who were shot may have had a family liking for firearms.

How to explain the other cases except as coincidences I do not know. Yet the fact remains if the deaths had been caused by the same disease, heredity, or family predisposition, would have been put forward as the cause. Two brothers of my acquaintance broke their arms and legs thirteen times between them. Each break was a separate accident, and the accidents extended over several years. Some peculiarity of the bony structure in both individuals probably accounted for the numerous fractures. Cases of suicide occurring in the same family, or cases of unaccountable disappearance, may be put down to similar mental conditions.

There is a cause for everything. What is the underlying cause that makes similar accidents happen to different members of the same family? *Quien sabe?*

PECULIAR FOREIGN BODIES IN THE VAGINA.

By WILLIAM J. ROBINSON, M. D.,

NEW YORK.

The following case seems to me worthy of record on account of several rather unique features.

Mrs. X brought her little daughter for examination. The latter is fifteen years old, very well developed, plump, her breasts being rather those of a young woman than those of a young girl. For several weeks she has been suffering from a yellow, ill-smelling vaginal discharge. The mother had noticed it about a month previously; how much before that she had it, she could not tell. But it is about a month since she noticed yellow stains on her underwear and bed sheets. She washed her genitals with borax, and then potassium permanganate, but with no benefit. When the daughter was asked if she had any pain, she answered no. When asked if she knew how the thing started, or if she knew of any cause of her trouble, she answered in a decided negative. She objected to being examined. I saw that I would achieve nothing and gain no information in the presence of the mother, so I asked the latter to step into the parlor for a few minutes.

I spoke to the little girl sympathetically, promised her absolute secrecy, pointed out the possible danger to her health of concealment and of refusing to be examined. She finally broke down and confessed that for the last two years she has been having regular sexual intercourse with a cousin, and that last summer she also had intercourse a number of times with a young fellow, one of her cousin's friends, who stopped at the same place in the country where they did. But she did not like that fellow, as he was a "tough"; and it was practically under force that she continued to have relations with him. Having yielded to him once, she was afraid that he would tell everybody, as he threatened he would, if she did not submit to him again. One time when she was alone in the house, her mother having gone to the city—she was to come back by a late train in the evening—he came in, made her drink some wine, had relations with her, but she remembered no particulars, for she soon fell asleep and woke up only late next morning. Soon after that she noticed the discharge, and she had quite a good deal of pain too, but she was afraid to tell her mother; she feared that her reprehensible behavior might be found out. I then asked her to let me examine her, and promised her that no matter what condition I found, her mother would never find out through me the cause of her trouble.

She agreed. The vulva and introitus vaginæ were swollen and eroded and very painful to the touch, and bathed in a greenish, very offensive discharge. Only after anesthetizing the introitus was I able to pass a speculum, which showed the cervix

to be highly inflamed and eroded. In introducing a cotton swab on the forceps a hard body was encountered in the posterior fornix. On removing the speculum and introducing two fingers I succeeded, not without difficulty, in removing a large walnut. But there could be felt another foreign substance. One after another I removed another walnut, three hazel nuts and a piece of sponge. The piece of sponge was extremely offensive in odor, so offensive that I feared I would faint. Only immediate opening of the windows and spraying with cologne relieved conditions a little. She remembered about the sponge, which she herself had inserted some months ago at the suggestion of a girl friend, but she denied absolutely any knowledge of the nuts. She was sure, however, that they must have been put in by that "tough" on the last night, after she fell asleep. An examination of the discharge showed it to be free from gonococci. The girl's humiliation when the foreign bodies were removed was deep, and her indignation was terrible. She promised that "he" would pay for it. I again spoke to her, I told her that she was running the risk of venereal disease, which would endanger her health and her life; also the risk of pregnancy, which would be terrible for her and the disgrace might kill her mother. She promised to behave herself and to leave boys alone, especially as "she did not care for them now." She only did it because a girl friend told her that all girls did it, and because the boys bothered so. I called in the mother, told her that her daughter had a little inflammation, due probably to a cold or some other unascertainable causes, but that it was nothing serious and she would soon be well.

I touched all the ulcerated spots with a 10 per cent solution of silver nitrate, then painted the cervix, vagina, and vulva with an aqueous solution of iodine, and ordered antiseptic injections twice daily. At the next visit the condition was greatly improved; there was still, however, considerable discharge, but not of an offensive character. I again painted the parts with iodine, and insufflated the vagina with a large amount of finely powdered kaolin—a procedure which I have found of great utility in inflammatory conditions of the vagina and cervix, of specific and non-specific origin. The antiseptic irrigations were to be continued. Two weeks later the little patient was entirely well.

This case is an illustration, one out of many, of the rapidly spreading looseness among the young of both sexes, in our large cities especially. It is not at all a rarity now to treat boys and girls of eleven to sixteen for various sexual diseases and disorders; teachers, of the East Side especially, tell us that sexual immorality is spreading at a terrible rate, that very many of the pupils, girls of twelve and fourteen years of age, practice intercourse frequently, and for pay, too. And they are shameless and brazen, and treat with indifference or contempt any rebuke that may be administered them. That the effect of such children on the good, normal pupils of the school cannot be otherwise than pernicious and ruinous goes without saying. Some method ought to be found of quickly suspending or segregating such pupils. But to bring charges against a pupil which it may be difficult to substantiate by documentary legal evidence might prove of serious consequence to the teacher, and, therefore, they—the teachers—prefer to take the path of least resistance, let matters stand as they are, and say nothing.

This case is also an illustration of the contemptible, vicious depravity of some men. It is not at all an uncommon practice for some vicious male brutes to insert foreign bodies into the vaginæ of women with whom they have relations. This is generally done without the knowledge of the victims, when they are asleep or under the influence of intoxicants of which they are induced to partake; and, unaware of any cause of trouble, those women often go about with those foreign bodies until dangerous inflammations and ulcerations have set in. And it is only on a vaginal examination that the *corpus delicti* is discovered, to the patient's intense chagrin and humiliation.

Another point that this case demonstrates is that by tactful sympathy one can accomplish a good deal more than by a high-horse, moralizing, threatening attitude; one can often save much lifelong unhappiness, much domestic infelicity, by a judicious act. How many heartaches, tragedies, and possible scandals are averted daily, only the physician, especially the physician specializing in certain lines of practice, knows. And he is silent, as it is his sacred duty to be.

12 Mt. Morris Park West

THE AUTOPSY:*

A LETTER TO THE PUBLIC

By RICHARD STEIN, M.D.,

NEW YORK,

VISITING PHYSICIAN TO THE GERMAN HOSPITAL

It seems but natural that the painstaking scientific physician, after having diagnosed and treated his patient's ailment with all the means at his command, after having followed up all the details of the case and committed himself to a favorable or unfavorable outcome (prognosis) should, when death ensues, be placed in a position to verify his diagnosis, or to be able to explain the reason of a mistaken prognosis by a post-mortem examination; or, if a diagnosis could not be made, to be able to clear up the nature of the fatal illness by means of an autopsy. Furthermore, if an operation had been performed and death ensues, the post-mortem examination will go far to demonstrate the reason of its failure to cure or to save the life of the patient. By this means the physician or surgeon is able to verify the accuracy of his judgment and to clarify his knowledge and experience. From this point of view, too, every case of fatal illness is an "interesting case," and may well be carefully investigated; and thus not only the rare or exceptional case calls for close study.

So it follows that post-mortem examinations should be looked upon as a duty by the medical attendant, the performance of which ought to be encouraged by the laity. If this standpoint be correct then the further duty devolves upon the profession to point out, from time to time, the obstacles which are constantly thrown in its path in the attempt to fulfill this duty toward the patient, the community and itself, so that the public may become conversant with the facts and be enabled to realize the difficult position of the medical adviser in this contingency.

It is the common experience of the physician, especially in private practice, that permission to perform autopsies is extended—if at all—in a be-

*Read at the clinical meeting of the German Hospital and Dispensary, Jan. 12, 1912.

grudging spirit, and only after long and disheartening parliamentation and contention with the relatives and friends of the deceased. In his efforts to shed light upon a case the doctor is often looked upon with suspicion, and, although it may be conceded that the results of the examination might have some general scientific value, these are not deemed of sufficient importance to justify a seemingly repulsive manipulation, and the much desired permission is consequently denied. In exceptional instances, it is true, permission is finally granted after an earnest plea has been made that the autopsy may reveal certain conditions which might prove of great value in the prevention or treatment of the immediate family of the deceased. Purely altruistic reasons, however, appeal only to the very few and strange to say more often to the poor and illiterate.

Aside from the lack of appreciation of the value of the autopsy for medical progress however, there are other and more general reasons why post-mortem examinations are not more generally encouraged. Everyone can readily understand the aversion to this procedure: the distress, the shock, frequently the overwhelming suddenness of death; the mystery of death in itself, the sanctity of religious custom and ceremonial, and above all, the abhorrence which is aroused by the thought of desecrating the remains—all these factors tend to raise an insuperable barrier to the performance of an unpleasant duty. At a time of mortal bereavement, too, the emotional side of human nature tends to predominate. It requires great exercise of tact on the part of the doctor to be able to broach the subject to the responsible members of the family. The attempt to uncover the truth of an obscure case is often met, if not with reproach, with distrust and disapproval.

The difficulties of the situation outlined above have been aggravated of late years by the fact that it has become customary to embalm very shortly after death has ensued. Thus the time available for obtaining permission to make the examination has in consequence been materially shortened. It is, furthermore, not to the interest of the embalmer to encourage the practice, as it interferes with his business, while formerly he would gladly lend a helping hand and would reassure the family that with the proper care disfigurement could easily be avoided. Under the present conditions autopsies must frequently be made after embalming had previously been done. This is a very disturbing complication for the pathologist.

It is not necessary to enlarge upon the importance of this subject. Pathological knowledge is the foundation of medical science. Most valuable opportunities, both of a purely practical, as well as general scientific interest, are sacrificed to indifference, ignorance and prejudice. The community is itself the loser. Let us hope that the new science of eugenics will help to point out and elucidate the true meaning of a subject which hitherto could only be reluctantly handled with the greatest delicacy and reticence by the medical profession. Withal, the conscientious physician with the proper scientific spirit is willing to learn even at a sacrifice. As to those members of the profession who neglect this matter, or show themselves indifferent, to them may be applied the remark of one of our most celebrated diagnosticians (Carl Gerhardt): "Only those physicians invariably make the right diagnosis who never make an autopsy." The doctor will not detract from his standing or his dignity, though he frankly admits that there is something to be learned at every autopsy.

In European countries most patients who enter the public hospitals do so with the understanding that examinations will be made in case of death. In our own institutions no such understanding exists, and great care must be exercised by the doctor in providing himself with adequate proofs of the agreement for such examinations in order to protect himself from public scandal and legal complications. Physicians and surgeons of many of our hospitals will testify to the difficulties encountered in the effort to obtain permission for such examinations.

It has been customary for hundreds of years to perform autopsies, but we are far distant from the time when the post-mortem examination will become a universal procedure, in line with the rapid progress of scientific effort. It is interesting to read the account of Jacques Cartier, for instance, one of the early explorers of North America. He performed a number of autopsies on members of his crew who had succumbed to a mysterious disease after landing in Newfoundland. Emperors and kings have been dissected for hundreds of years. The results of the autopsies were published in official reports. This was probably done in accordance with the law covering the demise of rulers.

No doubt the general enlightenment of the last centuries, the recognition, in part at least, of the importance of the necropsy for medical study and practice have been successful, to a certain extent, to overcome prejudice and false emotion, and even to set aside tender and sacred feelings in the interest of science. Still the universal introduction of this procedure, essential though it may seem to the progressive doctor, seems for the present impracticable or even visionary. In the state of the future, when matters pertaining to public health and hygiene will be strictly controlled the autopsy is destined to be a part of the measures instituted by the authorities. The law will then read about as follows: (1) It is the duty of the state medical examiner to certify to the death of every individual after making a personal examination of the deceased. (2) The body of the deceased, after the expiration of a reasonable time, shall be removed to a mortuary. (3) The state pathologist shall perform an autopsy in the presence of the attending and consulting physicians and surgeons, *in order to determine the cause of death.* (4) The body shall then be cremated.

70 East Seventy-ninth Street.

Glioma and Cerebral Traumatism.—M. L. Babonneix notes three theories as to the causation of glioma of the brain. The first is that of an unexplained congenital predisposition. The second is that an early leptomeningitis causes an irritation of the subjacent neuroglia. The third is that cranial traumatism causes a similar irritation of the cerebral substance. The author presents illustrative cases which suggest that glioma may appear after cerebral traumatism. Some authors attribute the production of glioma to the hyperemia or capillary hemorrhages which irritate the neuroglia. Others believe that traumatism alters the relations between the various tissue elements and separates from its normal connections an island of neuroglia, which becomes the tumor. Glioma so frequently follows cerebral concussion that this cannot be a mere coincidence.—*Gazette des Hôpitaux.*

THE BACTERIOLOGICAL PROBLEMS OF LEPROSY.

IT is now over forty years since Hansen demonstrated the presence of a bacillus in the affected tissues of the leper. Since that time the bacteriology of leprosy has constantly engaged the attention of all investigators of the disease, but it is only within comparatively recent years that any substantial additions have been made to our knowledge of this phase of the subject.

In the *U. S. Naval Bulletin* for January, 1912, Passed Assistant Surgeon Crow, of the Navy, gives an account of his work on the search for the microorganism in the general circulation of lepers. Out of a total of twenty-four inmates of the leper colony in Guam, he demonstrated the presence of the bacillus in the blood of all but three. His technique was carefully perfected, and it seems that all necessary precautions were taken to exclude contamination by substances which might contain other acid-fast bacilli. He concludes that if sufficient care and diligence be used, the lepra bacilli may be found circulating in the blood in at least 80 per cent. of cases. The constant presence of the bacillus in the leprous lesions has heretofore been regarded as the chief argument in favor of its being the cause of the disease. The work of Crow adds another link to the chain of evidence, and although, in this particular affection Koch's four postulates still remain uncompleted, there is, nevertheless, no reasonable doubt of the etiological connection between the bacillus and the lesions in which it is found.

The inability to propagate the bacillus artificially, either in laboratory animals or in culture media, has in the past presented the greatest obstacle to the final proof of this connection. Likewise, without this knowledge, intelligent studies in specific therapy have been impossible, and investigation of the manner of transmission necessarily limited to the keeping of clinical records. The work of Currie, Clegg, and Hollman of the leprosy investigation station in Hawaii seems now to be far enough advanced to warrant the conclusion that it will not be long before some truly specific treatment may be forthcoming. In an effort either to confirm or to disprove the statement of Clegg, who, as a result of independent work in the Philippines in 1909, claimed that he had succeeded in isolating in pure culture the lepra bacillus, the investigators at the Hawaiian station commenced, in 1910, a series of experiments which have not only tended to corroborate the independent work of Clegg, but also to contribute substantially to our knowledge of immunity in this disease. By adding leprous material to agar on which the cholera spirillum and amebas were growing in symbiosis, they found that they were able to cultivate an acid-fast bacillus which was morphologically similar to that of leprosy (*Public Health Bulletin, No.* 47). Furthermore, they have been able to isolate this bacillus in pure culture and by serum tests have proven that it is not identical with other members of the same group, represented by the smegma bacillus and the grass bacillus of Moeller.

From the fact that the organism which they have isolated can be grown from leprous tissue, together with its morphological similarity to *B. lepræ* as originally found in such tissue, it seems fair to assume that the two are, in reality, identical. This opinion is still further confirmed by the Hawaiian investigators' studies in immunity (*Public Health Bulletin, No.* 50). It had already been shown that the blood serum of lepers contains antibodies which, when combined with antigenic substances closely allied to those producing the Wassermann reaction, were capable of fixing the complement. Thus, Wechselmann and Meier were able to fix the complement by using syphilitic antigen and serum from leprous patients (*Deutsche medizinische Wochenschrift*, Vol. 34, p. 1347). The same result has been obtained by many other competent observers, and working along these lines the Hawaiian station investigators have been able to produce specific agglutinins for *B. lepræ*, by using the blood serum of a horse which had been injected with the cultivated lepra bacilli.

Therefore the identification of the organism may be regarded as absolutely proved, and from the premises in the case one would seem safe in predicting that the near future will see the successful issue of the effort to find an efficient serum or vaccine against the ravages of the one disease which has always, heretofore, been regarded as heading the list of incurable chronic affections.

TUMORAFFIN SUBSTANCES.

THE more recent studies by Ehrlich and von Wassermann in the chemotherapy of cancer serve to corroborate and are otherwise in harmony with work which has been done in past years and which passed largely unobserved by others. Neuberg, for example, has been at work upon the chemistry of tumors at the Agricultural High School, Berlin, since 1903, and early made the discovery that radium rays activate the autolytic enzymes of tumor cells. Along with workers in the Imperial Cancer Institute and elsewhere he also learned that other intracellular enzymes, notably lipases and oxidases, were similarly activated. The heightened production of coloring matters was evidently due to a similar mechanism. This quickening of intracellular activities taken in consideration with the cytolytic tendency of ferment action appears well calculated to antagonize the tendency of tumors toward unlimited growth and to be essentially curative. It was fur-

ther discovered in Salkowski's laboratory that the heavy metals possess properties similar to those of radium as far as effects are concerned, although naturally an entirely different mechanism may be involved. This property of the metals is brought in necessary association with the fact that they all tend to precipitate albumin in solution. As radium is in itself one of the heaviest metals it is assumed provisionally that its behavior may not be so dissimilar radically to that of its congeners as at first sight appears. The metals in question which have been tested include gold, platinum, lead, copper, silver, etc., certain preparations being able to stimulate or favor autolysis.

In the *Deutsche medizinische Wochenschrift* for February 22 Neuberg and Caspari review their own work along these lines. They appear to be the only investigators aside from Salkowski's students who have studied these properties of metals in connection with cancer cells with the exception of a Paris scientist, Gaube de Gers, who has very recently announced that colloid preparations of metals, especially of copper, will favorably influence cancer in man. No doubt this publication was responsible for the article by the Berlin investigators which apparently is partly in the interest of priority. They do not appear to have been prepared for a complete report and beyond stating that the preparations used are colloidal combinations of metals no information along this line is vouchsafed. The authors intimate that their preparations are decidedly milder in action than the eosin-selenium combination of Wassermann and are therefore much less likely to produce untoward effects. The changes set up in the tumor cells seem to be quite parallel for both kinds of reagent. As a general name for all substances of this character the authors use the adjective "tumoraffin."

EPIDEMIC CEREBROSPINAL MENINGITIS.

Epidemic cerebrospinal meningitis and acute poliomyelitis have been so prevalent in this country and in Canada during the past few years that the diseases are a matter of national concern. Effective measures for their control are lacking, while methods of treatment are eminently unsatisfactory. Consequently, investigations tending to increase knowledge as to these madadies is greatly to the interest of the general public. There has been recently published a reprint from Public Health Reports, January 26, 1912, dealing exhaustively with epidemic cerebrospinal meningitis, by Dr. W. H. Frost, Past-Assistant Surgeon, Public Health and Marine Hospital Service. The pamphlet is practically a compendium of all that is at present known of the disease and the methods of control and treatment, and as such is particularly valuable to the general practitioner.

With regard to the occurrence of the micrococcus of the disease, the results of investigations indicate the following conclusions: (1) Apparently healthy persons in the immediate vicinity of cases of cerebrospinal meningitis very frequently harbor the meningococci in the nasopharynx; (2) apparently healthy persons themselves not in contact with any cases of meningitis but residing in communities where an epidemic prevails are not infrequently found to be meningococcus carriers; (3) apparently healthy persons in communities where there have been only scattered cases of meningitis or none at all for several months are less frequently found to be meningococcus carriers; (4) the meningococcus is very rarely found in the throats of persons living in localities quite free from cases of cerebrospinal meningitis.

As to the use of serum in the treatment of the disease the observations of those best qualified to judge are thus summarized: (1) The serum when promptly and properly used effects a very substantial reduction in mortality, shortens the course of the disease, and reduces the proportion of disastrous sequelæ; (2) it must be used freely, repeated daily for at least three days in most cases, and as much longer as may be found necessary from observation of clinical signs and examinations of cerebrospinal fluid; (3) the best results can be obtained only by persons expert in the technique and principles of the treatment and conversant with the clinical aspects of the disease.

The most important part of the report is that which discusses public measures for the control of cerebrospinal meningitis. Two lines of procedure with this end in view may be considered. Preventive measures and treatment. Of course, from the public health standpoint, prevention is preferable, but even the most rigid preventive measures offer at best a very doubtful hope of materially decreasing the prevalence of the disease. Serum therapy, on the other hand, does justify the expectation of reducing the damage done by one-half, or even one-fourth. Frost, moreover, points out that there are special reasons why public health authorities should take an active interest in the serum therapy of cerebrospinal meningitis. The cost of the serum is sufficient to render it unavailable to the very poor. Likewise the proper scientific use of it, essential to good results, requires the services of experienced physicians and skilled attendants. Finally, the diagnosis and efficient control of treatment require expert bacteriological services which are not available in many communities, and when available are expensive. It is therefore believed that the most effective work which can be done by state and municipal health authorities toward controlling epidemics of this disease is along the lines of rendering assistance in its therapy. An outline of preventive measures is presented, although, as said before, such measures appear to be of little avail. The gist of the argument contained in the report is that reliance must be placed mainly on serum therapy in order to avoid damage from the disease as much as possible. And to obtain the best results from such treatment public health authorities should lend their aid.

THE DECREASE OF FERTILITY.

Herbert Spencer said that as a necessity of evolution fertility diminishes with that intellectual and moral development of the race which is comprised within the meaning of the word civilization. Darwin concluded that changed conditions of life have a remarkable specific power of acting repressively on the reproductive system. Doubleday published in England in 1841 a book in which he stated that

overfeeding decreases fertility, while on the other hand, a limited or deficient nutriment stimulates it. In all these dicta there is a half-truth, but they are only partly true.

In every civilized nation there exists a tendency to restrict reproduction of the species. There are causes which obviously work in the direction of reducing the birth rate. For example, postponement of marriage or avoidance of marriage, when these occur on a large scale are serious indications of the sociological trend, but do not explain the steady decrease of the birth rate which has taken place in France, and which is now taking place in Great Britain and among some classes of this country. Dr. A. Newsholme has written recently a small book on the subject, in which he states his view that the main cause of the modern very small family is that the parents, and especially one of the parents, does not wish for many children, and accordingly the limitation of the family is largely volitional. Undoubtedly the fact that a large proportion of the population live in cities is responsible to a considerable extent for small families. In New York and in other American cities there is a distinct relationship between small families and apartments. Apartments and large families for many patent reasons are not compatible. But it is not in this country and in France and England alone that the prevention of large or even fair-sized families is common; it prevails in all civilized lands.

Newsholme, referring to the suggestion that eugenics judiciously applied might prove the salvation of the civilized races, states that a precondition of any attempt to apply practically the important principles of eugenics with respect of any particular disease or defect, must be the collection of evidence on a sufficiently large scale which will fully justify intervention. The subject is large and should be regarded from every conceivable standpoint before opinions are openly expressed. One thing is certain, that in every country there is need for encouraging the propagation of the fit and discouraging the multiplication of the unfit, or in the course of time the best part of the population will be swamped. Unfortunately, it seems to be the unfit who are sedulously pampered to the detriment of the race as a whole.

PSYCHIC DISTURBANCES OF ANEMIC ORIGIN.

The conviction that many psychoses must be due to autointoxication has gained ground steadily as a result of the propaganda of Kraepelin and others. On the other hand, certain psychiatrists, while recognizing a somatic factor for the genesis of psychoses, are inclined to seek it in a vascular change, believing that variations in the blood supply must profoundly influence the metabolism of the nerve cells. At a recent meeting of the Breslauer Psychiatrisch-neurologische Vereinigung (*Berliner klinische Wochenschrift*, December 25) both Bonhoeffer and Schroeder read papers on the relationship between severe anemias and psychic disturbances. The former dealt with the clinical aspect of this sequence, while the latter described peculiar focal cerebral lesions which he had discovered in subjects dead of pernicious anemia. The doctrine that anemia if sufficiently severe is able to cause psychic disturbances is of course by no means new; and some psychiatrists have made the so-called exhaustion psychoses dependent on defective blood supply, just as the psychic disorders accompanying or succeeding acute infectious diseases are believed to be due to the action of exogenous circulating toxins. In both of these types it is assumed that the casual principle operates chiefly by altering the normal metabolism.

One of Bonhoeffer's patients had suffered long from intestinal hemorrhages and his hemoglobin was down to 30 per cent. The psychosis developed suddenly with anxiety, excitement, disorientation, hallucinations of sight and hearing, etc. The symptoms subsided spontaneously in a few days with partial amnesia. In four cases of pernicious anemia the symptoms showed notable individualization. One subject exhibited a twilight state, another anxious excitation of epileptiform character with rhythmic motor activity, a third had delirium followed by Korsakoff symptoms, and a fourth presented the picture of incoherent amentia. The disturbances were not of long duration. The cerebral lesions found by Schroeder could be conceived either as the results of minute hemorrhages due to the profound anemia or as miliary, necrotic foci with secondary extravasation of blood.

Bonhoeffer does not in this connection refer to the amentia which quickly supervenes when unusually large doses of bromides are ingested continuously. If this is regarded as largely the result of anemia of the brain, the suspension of the activity of the purely intellectual processes, without a corresponding effect on the emotional sphere and personality, should possess some significance in this connection, especially when contrasted with the opposite syndrome associated with cerebral hyperemia, in which mental activity is quickened but often dominated by the affect element.

SNUFF AND LEAD-POISONING.

Every once in a while there appears in the medical literature a report of a case of lead-poisoning, the lead being derived from some obscure and little thought of source in the environment of the patient. Now it is a housemaid who takes the first drink in the morning that falls ill while no other member of the household is affected; now an artisan who is engaged in some one part of a manufacturing process and who is stricken while all other workers are spared; now a painter's apprentice who sleeps in the back of the shop in company with pails and cans of mixed paint, etc. One such unusual case is reported by Eugen Stadler in the *Correspondenzblatt für Schweizer Aerzte* (Vol. XLII, No. 5). He observed in his hospital service a woman patient who has for several years suffered from headaches, dizziness, nausea, and vomiting, occasionally accompanied by severe abdominal pain, these attacks being usually interpreted as gallstone colic. She finally developed paralysis of some peripheral nerves and this with the typical blood picture, showing basophile degeneration of the erythrocytes pointed to lead-poisoning as the diagnosis. She soon recovered and returned to her

household, no other member of which was similarly ill. The source of the lead was not then discovered. A few months later the patient was brought back to the hospital, now suffering from a severe form of lead encephalopathy, from which she died. The clinical and blood pictures were again characteristic. This time the doctors were told that the patient was a passionate snuff taker, and an analysis of the snuff used by her showed remarkable contamination with lead derived from the lead foil wrapper. This, of course, explained why no other member of the household was affected, as none but the patient was addicted to this habit.

News of the Week.

Death Rate Remains Low in New York.—The records for the week ending March 2 show that the death rate for that week was 15.49 per 1,000 population, compared to a rate of 17.41 for the corresponding week of last year. There was an increase of 24 in the number of deaths from measles, but there seems to be no epidemic of that disease. Heart disease caused 191 deaths, or about the same as in 1911; pneumonia, 258 against 293 for 1911; tuberculosis 203, or three more than last year. There was but one death from whooping cough this year, as against 10 for the corresponding week of last year, and 19 fewer deaths from influenza. There were 408 deaths of children under five years of age, and 280 of persons over sixty-five years of age. There was a decrease of 104 in the number of deaths in the tenements and an increase of 46 in institutions.

New Jersey Health Officers Fight Rabies.—The Health Officers' Association of New Jersey has appointed a committee to continue the agitation aroused by the increase of rabies in the State. This committee met in Newark on March 5 for the purpose of drafting a bill that will be introduced in the Legislature urging strict quarantine of all dogs, and instructing the people concerning the nature of rabies, particularly in regard to methods of spreading it which are operative to the same extent in winter as in summer.

A Collective Investigation on Ozena.—At the meeting of the Third International Laryngological Congress, held in September, 1911, in Berlin, Germany, it was unanimously resolved that a universal investigation on the subject of ozena should be made, and the full report, statistical and otherwise, be presented at their next Congress, to be held in Copenhagen. An executive committee was appointed to assume charge of the investigation, consisting of Prof. Rosenberg, Prof. Grabower, and Prof. Alexander, all of Berlin. These have in turn appointed laryngologists to assume charge of these investigations in their various countries. Among these so appointed are Professors Chiari, for Austria; Onodi, for Hungary; Mahu, for France; Brown-Kelly, for England and Colonies; Hellat, for Russia; Pieniaczek, for Poland; Gerber, for East Russia, etc., and Dr. Emil Mayer for the United States of America. The latter, after conferring with the presiding officers of our three large National Laryngological Associations, secured their prompt and hearty cooperation, and their endorsement of the following executive committee: Drs. Joseph Gleitsmann, Robert C. Myles, and Harmon Smith, representing the American Laryngological Association; Wolff Freudenthal, Thomas J. Harris, and H. Holbrook Curtis, the American Laryngological, Rhinological and Otological Society; Sidney Yankauer, the Academy of Opthalmology and Oto-Laryngology. Representative laryngologists will be appointed from the various states of the Union, who will investigate as to the relative frequency, etc., of this disease in the United States, and to this end examinations will be requested of school children, inmates of asylums, almshouses, prisons, reformatories, etc. These reports when completed will be sent to the chairman of the committee.

A New Italian Hospital.—The Italian Benevolent Society of this city has purchased five houses in East Eighty-third street and will remodel them for use as a hospital. A morgue and autopsy room will be in the cellar, and the board room, offices, and dispensary on the first floor. The second floor will contain the doctors' quarters, the children's ward and obstetrical ward; the third floor will be given over for the use of women and will contain surgical, private and medical wards for women. The fourth floor will be for men and will have a surgical and private wards, and operating room and an anesthesia room for men exclusively. On the fifth floor will be ten private rooms and a private operating room.

The Robert Dawson Evans memorial building for clinical research and preventive medicine, a part of the Massachusetts Homeopathic Hospital, was dedicated and opened Wednesday of last week. Addresses were made by Governor Foss, Lieutenant-Governor Luse, Mayor Fitzgerald of Boston, President Maclaurin of the Massachusetts Institute of Technology, President Murlin of the Boston University, and Dean Sutherland of the Boston Medical School. Dr. Frank C. Richardson is the director of the memorial. There are five laboratories in the building—neurological, physiological, pathological and bacteriological, chemical, and pharmacodynamic—all in close connection with the wards of the hospital. A prominent feature of the work of the institution will be the department of public education in hygiene and health matters, under the auspices of which popular lectures on tuberculosis, sex hygiene, dangerous diet, paternity, maternity, etc., will be given. The building is a memorial given by Mrs. Maria A. Evans, widow of Robert Dawson Evans, who died July 6, 1909, from injuries received when he was thrown from his horse. In his address Dr. Maclaurin of the Massachusetts Institute of Technology defended this country from the popular imputation of its being a "land of dollars," "for it is true," he said, "that nowhere in the world is wealth so nobly given for great causes—the spread of education, the advancement of science, the encouragement of art, and the alleviation of suffering. An institution, we have been taught, is the lengthened shadow of a man. This one will indicate to generations yet to come the real bigness of the man it commemorates. It will show his breadth of vision, his keen look into the future, his sympathy with humanity, his faith in research and in scientific education. It is an institution that can never die and it is one that will keep the name of Robert Dawson Evans in grateful memory forever."

New Dispensary Building Opened.—The Medico-Chirurgical Hospital of Philadelphia opened its new dispensary building for inspection on March 7. The structure has a frontage of 59 feet and a depth of 140 feet, with a total floor space of 10,000

square feet. It is intended for the treatment of children's diseases, affections of the eye, diseases of the nervous system, deformities of bones and joints, diseases of women, medical, surgical and cutaneous diseases, and diseases of the ear, nose, and throat.

The William Pepper Medical Society of the University of Pennsylvania held its 25th annual reunion on March 7. Dr. George W. Norris presided and acted as toastmaster. Responses were made by Dr. Alfred Stengel, Dr. Richard C. Norris, Dr. B. Franklin Stahl and Dr. Joseph Bloodgood of Baltimore.

Professor Selskar M. Gunn, Assistant Professor of Biology at the Massachusetts Institute of Technology, has been appointed editor of the *Journal of the American Public Health Association.* Mr. Gunn is a graduate of the Institute in 1905, and after completing his course under Professor Sedgwick spent a year in the Boston Biochemical Laboratory, where he had much experience in industrial biology. In 1906 he became first assistant bacteriologist to the State Board of Health of Iowa and lecturer in hygiene and sanitation at the Iowa State University. Early in 1908 he was called to the place of health officer at Orange, N. J. Last summer he was commissioned by the mayor of Milwaukee to make an efficiency investigation of various of the city's public departments.

Pay for Reporting Births.—The Board of Commissioners of Cook County, Ill., has made an appropriation to pay physicians for reporting births, the amount to be paid being 25 cents for each report.

Health Inspectors to Be Physicians.—The San Francisco Health Board decided that all or most of the sanitary inspectors of the city shall be physicians who will give all their time to the work. The pay of the inspectors has been raised from $125 to $200 a month.

Enlarging the Registration District.—The Mississippi Legislature on February 29 passed a bill creating a Bureau of Vital Statistics to be under the jurisdiction of the State Board of Health.

Health Officers Alleged Violators of Health Laws.—An indictment for violation of the State sanitary laws has been brought against a physician and health officer of Shreveport, La. A health commissioner of Passaic, N. J., has been arrested on a technical charge of disorderly conduct brought by the Board of Education on account of his refusal to permit his little daughter to be vaccinated. The president of an anti-tobacco society of this city has lodged complaint against Dr. O'Connel, the newly appointed quarantine officer of this port, alleging that he broke the rules of the Board of Health office in this city by smoking inside the building. The Oklahoma City quarantine officer has been complained of by the Oklahoma County Medical Association because he warned the mothers of children exposed to diphtheria against the use of antitoxin, alleging that the results of its prophylactic administration was frequently disastrous.

A Clean-Up for Texas.—Dr. Ralph Steiner, State Health Officer of Texas, issued an appeal recently urging the observance of Saturday, March 9, as a "clean-up" day throughout the State. The clean-up day for 1911, he says, proved a great success. Many of the cities and towns of the State not only observed the day named, but devoted two weeks to the work of removing and destroying the accumulation of the winter months, preparatory to the coming of warmer weather.

The German Medical Educational Trip will be taken this year in America. The members will leave Hamburg on September 7 on the *Cincinnati* and returning will leave New York on October 10 in the *Victoria Luise.* The places to be visited are New York, Philadelphia, Atlantic City, Baltimore, Washington, where the travelers will take part in the International Congress of Hygiene and Demography; Chicago, Niagara Falls, Montreal, Boston, and Albany. The cost of the entire trip will be only 1,950 to 2,250 marks ($485 to $560).

A Correspondence Course in Medicine.—At the meeting of the Association of Medical Colleges in Chicago on February 28, Dr. W. P. Harlow of the University of Colorado, in his presidential address, advocated the establishment of a post-graduate correspondence course for physicians intending to take a clinical or laboratory course later. Much of the valve of a post-graduate course was lost, he said, because the physician came to it without sufficient knowledge and without the preliminary training which could be given by correspondence at a saving of much time.

"Adenoids in School Children and Their Effect Upon the General System."—Dr. G. B. Taylor of Cameron, Texas, writes that in his article with the above title, published in the MEDICAL RECORD of February 17, 1912, he neglected to give credit for several quotations from an article by Dr. E. B. McCready of Pittsburgh, published in the issue of September 2, 1911.

Osteopaths Must Be Licensed in New York State.—The New York State Osteopathic Society at its semi-annual meeting in Albany on March 9, passed resolutions to prosecute any one undertaking to practice osteopathy without having complied with the educational standing established by the State Board of Regents. This will be the first time that prosecutions under the law of 1907 have been undertaken by the osteopathic society.

The Passing of the Common Drinking Cup.—On March 1 the Missouri law went into effect forbidding the use of common drinking cups, roller towels, and common brushes and combs in public places and on railroad trains. Missouri is the twenty-third State to abolish the common drinking cup in the stations and cars of all railroads operating within its borders.

National War Against Mosquitos.—At the coming meeting of the National Drainage Congress in New Orleans in April, a movement will be inaugurated to restrict the breeding of mosquitos by drainage of the 80,000,000 acres of swamp land and 100,000,000 acres subject to annual overflow in the United States. An effort will be made to place Col. Gorges in charge of the sanitary division of this reclamation movement.

Dr. Ernst J. Lederle, Health Commissioner of New York, and Dr. G. A. Soper, president of the Metropolitan Sewerage Commission, are among the heads of city departments who will speak in a series of lectures to be given at Columbia University on Monday afternoons this month and next.

The Distinction Between Christian Science and Quackery is not sharply drawn in Switzerland. A dispatch to the *New York Times* says that "Doctor" Joseph Unterberger, a Christian Scientist, advertising himself as a "natural healer of all diseases," has been tried at the court of the Canton of Appenzell for causing the death of a woman "by lack of medical knowledge and neglect" and sentenced to a year's hard labor and costs. He is

expelled from the canton and is prohibited from exercising his "profession" in Switzerland. This sentence is under the new Swiss civil and penal code, which is severe toward persons of the charlatan class, who formerly escaped with light sentences and fines.

Delegates to the Rome Tuberculosis Congress.—Acting Secretary of State Wilson has appointed six delegates to represent the United States at the seventh International Congress on Tuberculosis, to be held in Rome, April 14 to 26. The delegates appointed are Dr. Henry Barton Jacobs of Baltimore, secretary of the association; Dr. Livingston Farrand of New York, executive secretary; Dr. Charles L. Greene of St. Paul, Dr. G. Walter Holden of Denver, Dr. Gerald B. Webb of Colorado Springs, and William H. Baldwin of Washington, all directors of the association.

Manhattan Medical Society.—At the meeting of this Society, to be held at Reisenweber's, Fifty-eighth street and Eighth avenue, on the evening of Friday, March 22, at 8:30 P.M., Professor White of the George Washington University Medical School, Washington, D. C., will read a paper entitled: "Mental Medicine in General Practice." The discussion will be by Drs. Jelliffe, Gregory, Bailey, and Casamajor. The medical public are invited to be present.

Confederate Army Surgeons to Meet.—The Association of Army and Navy Surgeons of the Southern Confederacy will hold their annual meeting in Macon, Ga., in May. Dr. E. D. Newton of Atlanta is president of the association.

The Henry County (Ia.) Medical Society, at its annual meeting held in Mount Pleasant on February 29, elected the following officers: *President,* Dr. F. R. Wilson of New London; *Vice-President,* Dr. G. M. Van Ausdall of New London; *Secretary and Treasurer,* Dr. O. A. Geeseka of Mount Pleasant; *Censors,* Drs. J. N. Day, L. B. Allen, and W. A. Sternberg of Burlington; *Delegate to the State Society,* Dr. F. C. Mehler of New London; *Alternate,* Dr. C. F. Applegate of Mount Pleasant.

The Miller County (Ark.) Medical Society, at its annual meeting in Taxarkana on February 29, elected the following officers: *President,* Dr. J. A. Lightfoot; *Vice-President,* Dr. R. H. T. Mann; *Secretary and Treasurer,* Dr. L. J. Kosminsky.

Charitable Bequests.—Mount Sinai Hospital and the German Hospital are named as beneficiaries to the amount of $5,000 each under the will of the late Ernest Thalmann.—Under the will of Bernard Rothenberg, Mount Sinai Hospital is to receive $400, the Lebanon Hospital, Beth-Israel Hospital, the Home for Aged and Infirm Hebrews, and the Montefiore Home for Chronic Invalids receive $200 each, and the United Hebrew Charities $100.—The Tuberculosis Preventorium for Children announces the completion of its building fund of $150,000. The final subscriptions were $1,000 from Mrs. Henry Phipps, $500 from Emerson McMillan, and $1,000 in small amounts from other contributors.—By the will of the late Louise M. Spear of Philadelphia bequests are made as follows: White Haven Sanitarium for Poor Consumptives, $5,000; Children's Seaside Home for Invalid Children at Atlantic City, $2,000; Mercer Memorial Home for Invalid Women at Atlantic City, $2,000; Presbyterian Seaside Home at Cape May, $2,000; Home for Incurables, West Philadelphia, $2,000; Home of the Merciful Saviour for Crippled Children, $1,000. The income from a sum of $2,000 is bequeathed to a sister, the principal to revert to the German Hospital on the death of the legatee.—By the will of the late Josephine Drexel of Philadelphia the sum of $20,000 is bequeathed to the Archeological Museum of the University of Pennsylvania, $50,000 to the trustees of the University to be used for such purposes as they deem best, $10,000 to the Hospital of the University, $10,000 to the Catholic University of Washington, D. C., $10,000 to the Gynecean Hospital of Philadelphia, $5,000 to the St. Joseph's Day Nursery, New York.—By the will of the late Julius M. Seidenbach, of Philadelphia, the sum of $1,000 is bequeathed to the Jewish Foster home and Orphan Asylum and to the Jewish Hospital Association and the sum of $500 to the Jewish Maternity Association.

The Late Dr. Weber.—At a meeting of the Board of Directors of the New York Post-Graduate Medical School held March 7 the following resolutions were adopted: "*Whereas,* We have learned with deep regret and sorrow of the death of our esteemed associate and colleague, Dr. Leonard Weber, who for many years gave his best efforts to this institution, and *Whereas,* Dr. Weber was a man of high honors, exceptional ability and integrity, beloved and respected by all who knew him for his many scholarly attainments, his geniality and his sincerity; therefore, be it *Resolved,* that we record this sad tribute to his memory, and join in expressing to his bereaved family our sincere sympathy; and be it further *Resolved,* that these resolutions be spread upon the minutes of this faculty, and a copy transmitted to the members of his family as a token of our respect and a reverence to his memory." Signed, H. J. Boldt, M. D., George G. Ward, Jr., M. D., Committee.

Obituary Notes.—Dr. George Stanton Hamilton of Lakota, Va., died on March 4, at the age of eighty-two years. He was a graduate of the Jefferson Medical College of Philadelphia in 1851.

Dr. A. C. McDowall of Lyndonville, Vt., died on March 2, at the age of forty-seven years. He was graduated from the medical department of the University of Vermont in the class of 1890, and after practising for a few years in Barnet, settled in Lyndonville.

Dr. William J. Hughes of Leicester, N. C., died March 4, at the age of fifty years. He was a graduate of the Kentucky School of Medicine, Louisville, in 1885.

Dr. William J. King of Golden, Colo., died February 28, at the age of thirty-nine years. He was a graduate of the Denver College of Physicians and Surgeons in the class of 1897, and was professor of pediatrics in the same institution at the time of his death.

Dr. Henry B. Dwelle of St. Louis died March 2, at the age of eighty-five years. He was a graduate of the Medical College of the New York University in 1856, and had practised in St. Louis for over half a century.

Dr. Edwin Green of Arcadia, Fla., died February 24, at the age of sixty-six years. He was a graduate of the Kentucky School of Medicine, Louisville, in the class of 1882.

Dr. Arthur Lee Macken of this city died of apoplexy on March 7, at the age of forty years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1904.

Dr. Howard C. Spencer of Gainesville, Fla., was found shot on a lonely road about five miles from town on February 26. He was fifty years old, and

was a graduate of the Eclectic Medical Institute, Cincinnati, in 1893.

Dr. GEORGE B. MAXWELL of Attleboro, Mass., died February 29, at Fort Worth, Texas, at the age of fifty-two years. He was graduated from the Chicago Homeopathic Medical College in 1894, and practiced in San Francisco for several years before removing to Attleboro.

Dr. THOMAS G. MCCONKEY of San Francisco died on February 28, at the age of fifty-three years. He was a graduate of the medical department of the University of Pennsylvania in 1890.

Dr. SAMUEL A. JONES, formerly dean of the Homeopathic Medical Department of the University of Michigan, died at his home in Ann Arbor on March 9, at the age of seventy-eight years. He was a graduate of the Pennsylvania Homeopathic Medical College, of Philadelphia, in 1860.

Dr. R. W. WALMSLEY of New Orleans died February 27, at the age of fifty-five years. He was born in Dubuque, Iowa, and was graduated in medicine from the University of Louisiana, now Tulane University, in 1881. For several years after graduation he practiced in New York, but returned to New Orleans in 1894.

Dr. FRANK G. BURNETT of Pawtucket, R. I., died on March 3, his death being hastened by grief over the death of his twin brother, Dr. Fred. N. Burnett of Attleboro, Mass., a few days previously. He was born in 1860 and was graduated from the Medical College of the New York University in 1885. He began practice in Windsor, Conn., but removed in 1882 to Pawtucket.

Correspondence.

OUR LONDON LETTER

(From Our Regular Correspondent.)

INSURANCE TROUBLES—THE REPRESENTATIVES OF B. M. A. MEETING—DECISION TO ENFORCE CLAIMS—THYROIDECTOMY—VACCINE TREATMENT.

LONDON, Feb. 23, 1912

I FEAR you are getting tired of hearing about our insurance troubles. We are "sick of them all" according to every doctor you meet. Yet they all persist in dragging them into every conversation and not a few pour their solutions into letters to the journals and even newspapers, for since the *Times* opened its columns to medical correspondents, it seems respectable to do so. The end of the fight is not exactly in sight. The representatives' meeting of the B. M. A. opened on Tuesday. Formal business was transacted and then the chairman (Dr. Maclean) vacated the chair while the representatives discussed a motion censuring his direction at the November meeting and the course he took as to the late secretary's appointment as deputy chairman of the Insurance Commissioners. Dr. Maclean admitted that perhaps he had erred in November, but the rapid progress of the bill permitted no time to consult the representatives, and he thought it necessary they should act in consonance with what they believed their constituents would desire. He repudiated any desire to conceal the exact position as to the appointment of Mr. Smith Whitaker. The vote was rejected and Dr. Maclean resumed the chair. The meeting went to work in earnest, and with over 350 items on the agenda you will not wonder that it had to sit (with brief intervals) all day—indeed until late at night. It was expected to occupy Wednesday also, but so many points had to be discussed that it continued over the whole of Thursday morning. Obviously a three-days' debate cannot be comprised in a few sentences and the conclusions only can be given to-day as they seriously affect the profession. A state sickness insurance committee has been set up.

By far the most important action of the meeting was the resolution which accepted practically the demand for an amended act—thus endorsing the views of the Reform Committee and other outside bodies against those of the council. This resolution, carried by 159 votes to 3, is significant. It directs the council to inform the commissioners in unmistakable language that unless the minimum demands of the association be embodied in the regulations in such a manner as shall be effectual and permanent, *with a view to having them embodied in an amending act*, it is the intention to call upon practitioners to decline to work the act. This is what over 26,000 practitioners have agreed to.

It was further decided that complaints against medical men must be considered by a medical committee; that the right of dispensing should remain with those who desired to retain it; that the administration of medical benefits shall not be under the control of Friendly Societies.

With regard to remuneration, the policy was agreed on to claim a minimum capitation fee of 8/6, not including medicines, appliances and other extras, with an income limit of £2 a week.

The Royal Colleges here and the Scottish colleges and corporations are uniting in a committee respecting the act. The Apothecaries Society has joined and universities have been invited and will probably fall in. Mr. Lloyd George's attack on these bodies has perhaps hastened their movements. His attack on "the doctors" as a set of Tories who ought not to interfere in politics, has helped to bring about the greatest degree of union that has ever been obtained in the profession.

The position of hospitals under the act continues to excite alarm for their funds. Yesterday at the annual meeting of the Charing Cross Hospital the chairman urged upon the governors that extension of their work could not be undertaken in view of the danger ahead.

On the 13th inst. there was a joint meeting of three sections of the Royal Society of Medicine, viz., the surgical, medical, and that devoted to anaesthetics. They met to consider a paper sent by Dr. T. P. Dunhill, of Melbourne, on partial thyroidectomy under local anesthesia with special reference to exophthalmic goiter. Dr. Dunhill has done 380 such operations, and of these 230 were for exophthalmic goiter. There were 4 deaths out of the 380 operations and for each death an accountable cause. The first from removing too much tissue and crushing when he was not expert; his second, from bronchitis; a third was moribund; the other cannot be published at present. When he began the operation was considered rather dangerous and was not often performed. He had been feeding patients on the milk of goats from which he had removed the thyroid and had a number of cases among his out-patients, when one day a woman exceedingly ill, with no living relatives, begged him to do anything to relieve her. The whole position being placed before her, she begged for operation. Some who had seen her got permission to visit her afterwards in the ward and one after another asked to be operated on, and eventually all

the other cases who knew her in the out-patient room were surgically treated.

He divides the cases into four classes: First, the classical type, but without organic degeneration, and in which recovery is not impossible; second, cases in which thyroid degeneration has taken place; third, when the thyroid is quite small or scarcely detectable and there is an extreme degree of one or more characteristic signs; fourth, cases with thyrotoxic symptoms associated with a goiter, which is not truly exophthalmic. In class one Dr. Dunhill refuses to operate until medical treatment has been fairly tried —say three months, if effectually carried out; one man he kept under it for 12 months. In class two, every stage of wreck may be met with, and most men decline to operate, as they think it dangerous and organic disease has gone too far for improvement to follow. He has done 19 operations on such cases and great improvement has followed. The third class offer more difficulty to decide. In the fourth the response is immediate and complete.

He urged that to regard operation as *only* a last resort is erroneous, and such an opinion takes away many a patient's chance. So long as it prevails cases will be continually progressing from class one to two, and he has had cases sent to him when they were really dying and some did die as soon as they were in the hospital. How much gland tissue should be removed? Enough to cure the disease, says Dr. Dunhill. In young persons, not very bad, one lobe, with any mid-lobe or isthmus. In older patients, very bad, that will do no good. One lobe and half of the other must be taken away, and if the gland has been big and active the half left may be too much. At the same time this operator says one must not be hustled into removing too much just to "make a complete job at once." Remember more can always be removed, but it cannot be put back again. In three early cases he removed a third portion and thinks it was wiser thus to feel his way. He thinks, too, that if the removal is rapid and gentle, one and a half may be less dangerous than one only, for the loss of one causes reflex dilatation of the vessels of the other with increased glandular activity and the remaining lobe being encapsulated tightly, must pour the results of excessive activity into the lymph and blood streams with consequent poisoning. If all of one lobe and one-half of the other are taken "*without crushing*," the cut surface of the second leaves a way of escape to the exterior through an efficient drainage tube. This, he says, would not hold good with slow operating or rough handling. One lobe removed may do no good because too much thyroid tissue remains, and that is why many operations are called unsuccessful. The fear of myxedema following is spoken of, but we hear of no cases of it. Patients are soon able to resume and enjoy their usual life; they play tennis, ride, dance; one man is building coaches; another is blacksmithing. With few exceptions local anesthesia was used. With nervous patients he sometimes put the general anesthesia apparatus on a shelf and told them they could have it when they liked. They never asked for it, so he gave up preparing for it. Local anesthesia means using seven ounces of 2 per 1,000 novocaine and well infiltrating all the front of the neck.

Captain R. McCarrison, M.D., I.M.S., contributed a paper to the medical section (R.S.M.) on the 23d inst. on the "Vaccine Treatment of Simple Goiter." In previous researches he had traced the disease to an infecting agent in the intestinal canal and shown that amebic infection abounded in most cases of goiter in Gilgit. In his early work the vaccine used was a composite one obtained from the feces of goitrous persons. It had the characters of the coli group, but differed from *B. coli* by not producing indol. An Australian pony imported into Gilgit was found to have goiter and Capt. McCarrison isolated from its feces a spore bearing organism which was commonly met with in human cultures. He has treated 33 selected cases by vaccines—the composite one giving the best results. The local reaction is not marked if the initial dose be small—150,000,000- in 5 minims of salt solution. Injected into the upper arm the patient can usually follow his employment. From four to seven inoculations may be needed, but some cases were cured by two or three. All the cases remarked on the feeling of *bien être* they experienced. Usually an autogenous vaccine was employed, but excellent results had also been obtained by vaccine from another patient. Metchnikoff showed that some microbes in our normal intestinal flora produce toxins. Capt. McCarrison holds that the thyroid secretion neutralizes these. When to them is added the specific virus of goiter, an extra strain is thrown on the gland. The several vaccines relieve the thyroid of part of its normal work and so enable it without continuing in a state of hypertrophy to destroy the specific virus of goiter. The nervous and other degenerative changes which follow thyroid incompetency are due to toxic substances absorbed from the alimentary canal and are not neutralized by the imperfect functioning of the thyroid.

Dr. P. Weber suggested that thyroid feeding would have the same effect if the explanation proposed were correct.

Dr. Langmead made some remarks on the connection of thyroid hypertrophy with toxemia.

Mr. J. Berry admitted that some cases might have to be submitted to the surgeon, but he ought never to operate until after prolonged medical treatment had proved absolutely useless. He thought a few cases were not hypertrophic, but rather allied to atrophy, the vesicles being filled with stagnant secretion and the distention rendering the cells inactive.

Dr. Taylor (president) said it might be expected that there was some underlying factor common to the different methods of treatment.

Dr. Robt. Hutchinson was doubtful of intestinal toxemia. Thyroid secretion stimulated oxidation in the body and conditions which increased metabolism might just as likely lead to thyroid enlargement.

Dr. Crookshank asked if spontaneous cure occurred in Gilgit?

Capt. McCarrison said goiter in Gilgit Valley was the same as elsewhere. Cretinism was common and goiter appeared in 40 per cent. of cretins. He had never seen goiter disappear spontaneously. Twenty per cent. of recruits imported to Gilgit got goiter and a few of them got well when the enlargement was very slight.

A Peculiar Manifestation of the Pasteur Treatment for Rabies.—C. Frugoni and C. Gargano observed in about 5 per cent. of the patients treated by means of prophylactic antirabic injections that ten to twelve days after the injection there appeared at its site a painful swelling, which disappeared at the end of three or four days. With every succeeding inoculation the swelling reappeared. Abscess formation and fever were never noted. The authors believe that this phenomenon is one of anaphylaxis.—*Rivista Critica di Clinica Medica*

The Clinician, the Hospital, and the Medical School.—D. L. Edsall notes that great usefulness as a teacher may go together with great skill as a practitioner, but one does not imply the other, and when either of these activities is made more exacting, the other must be restricted both in order to give proper thought to one's work and especially in order to keep trained for the work, for if training stops, progress halts also. While the life of the teacher and investigator usually increases his value as an adviser to difficult and unsolved problems, it often decreases his skill in carrying out the home details of family practice, because it takes his time and thoughts away from these; and devotion to practice makes a man similarly unfit for exacting teaching and investigative work. Clinicians who are in practice necessarily make their practice their first interest if they secure it, or hold it when they have secured it, and their teaching and research must suffer since they take a secondary place in their lives and thoughts; and when great success in practice comes they are pushed more or less completely aside by the pressure of the more absorbing activity. This is the usual history of clinical teachers in this country. The two important things that any co-operating hospitals are asked to do are (1) to give their chiefs of staff liberty to carry out their work in the way that their professional training indicates is best, and to impose upon them rather than upon the administration the responsibility for the medical details. (2) They are asked to appoint to their staffs only men who will be acceptable to the medical schools. As to provision for the material needs of the chief and his assistants; they will require salaries sufficient to permit them to restrict their practice absolutely to consulting work, and to make this secondary, in both time and thought required for it, to their academic work. With a suitable combination of the German academic system and something approaching the English ward clerk system, the best results now possible for both students and medicine would be obtained in this country as well as elsewhere.

Convulsive Tendencies During and After Encephalitis.—W. P. Lucas and E. E. Southard have searched the records of the Children's Hospital of Boston from 1905 to the present date for possible instances of encephalitis. Cases of "encephalitis", "toxic encephalitis", "meningitis?", and "encephalitis?" have been considered. Twelve cases have been chosen. These show onset always sudden; paralysis or paresis in all cases (oculomotor paralysis in 7); deep reflexes altered in 10; mental symptoms in 10; rigidity of the neck in 9; general convulsions in 7 (absent in 4); nausea or vomiting in 5 (not noted in 7). The results fall into three groups: (*a*) Death during acute attack in 2 cases. (*b*) Recovery from acute attack, with subsequent epilepsy and mental deficiency, and death after twenty-one months in 1 case. (*c*) Recovery from acute attack, with residual symptoms in 5 cases; 2, normal, except for strabismus and possible slight mental change; 2, epileptic and mentally defective. With respect to epilepsy, the total incidence of convulsions during the acute attack was 7 in 12. Of 9 cases still living, 5 showed convulsions during the acute attacks, and 2 of the 5 are epileptic. In both epileptic cases there was a brief interval between recovery from the acute attack and the onset of epilepsy.

Face-Piece for Nitrous Oxide.-Oxygen Anesthesia.—W. W. Boothby states that the requirements of a nitrous oxide-oxygen apparatus that would produce a surgical anesthesia with the patient relaxed in all cases are as follows: The apparatus must be capable of delivering constantly the desired amount of nitrous oxide and oxygen by merely setting one valve for each gas; that it must continue to deliver this same amount as long as desired without further attention; and that it be possible, instantly and independently, to change the rate of flow of each gas. In order to be able at a glance to estimate the relative rate of flow of each gas, the mixing chamber must be of glass containing water and the pipes so arranged that each gas bubbles into the chamber separately. It is well recognized that to produce relaxation in all cases ether vapor must be given in addition to the gas-oxygen in a certain number of cases; it is also recognized that different cases may require amounts of either vapor varying within wide limits, and further, that it is necessary to be able gradually and yet rapidly to vary the ether percentage. The apparatus must be light and portable. And finally, the face-piece must be air-tight and at least partly self-retaining. The author describes a face-piece or rubber collar that he has designed to meet the last requirement, namely, that of preventing air from leaking into the gaseous mixture between the face and the mask, while at the same time retaining the latter in place. It is a modification of the Gatch cuff.

Chronic Excessive Intestinal Putrefaction as a Factor in the Production of Disturbances of the Nasal Mucous Membrane. S. Floersheim.
Sarcoma of the Testicle, with Report of a Case. A. C. Stokes.
Iodine Fumigation. C. J. Kœnig.

Functional Disorders and Neurosis of the Stomach.—J. Kaufmann warns one against making a diagnosis of gastric neurosis because the patient happens to be a neurasthenic. A patient may present the appearance and characteristic symptoms of neurasthenia and at the same time harbor a gastric ulcer or carcinoma. A further factor which frequently proves misleading in these cases is the negative result of examination. Even when the results of all examinations are negative one should accept the diagnosis of gastric neurosis only with a good deal of mental reservation. The author states that the vast majority of ulcer and cancer cases which have come to his knowledge were previously diagnosed as gastric neurosis. In many of the conditions erroneously described as secondary or symptomatic gastric neurosis, the disturbance of the gastric function must be attributed much more to disorders in the chemistry of the body than to a derangement of the nervous apparatus of the stomach. There are disorders of the gastric function caused by the different forms of anemia; by acute as well as by chronic infections, particularly tuberculosis; by chronic intoxications and autointoxications, as illustrated in chronic nephritis, diabetes, etc.; by metabolic disorders, gout, etc., and by changes in internal secretions (Graves', Addison's disease, etc.).

Intraabdominal Conditions Presenting Acute Manifestations.—N. Jacobson states that no part of the body is subject to such a variety of acute emergencies as the abdomen. The urinary bladder, as well as the gall-bladder, are occasionally ruptured by force, while blows upon the abdomen, or even severe jars, are capable of causing a rent in the stomach or intestines, even though the surface may remain intact. Evidence of injury to the diaphragm may be so obscure as to leave the medical attendant in doubt

as to its nature. Rupture of the intestines may occur without injury to the abdominal wall. The two most significant signs of acute intraabdominal mischief are intense, agonizing pain and muscular rigidity. Perforating gastric or duodenal ulcer is more frequently overlooked than is any other acute abdominal catastrophe. While one may be satisfied that one is dealing with some form of perforation, the site of the latter may be obscured by the developing signs of peritonitis. Of the inflammatory conditions in the upper abdomen the one most frequently recognized is acute cholecystitis. As a rule, in this condition one is able to obtain a history of previous gallstone colic, with evidence of obstruction and consequent distention and swelling of the gall-bladder with local tenderness.

The Specialist and the General Practitioner.—W. S. Gottheil concludes that a large proportion of the specialist consultation cases are instances in which a single examination and advice based thereon, or an isolated treatment, are insufficient, unfair to the patient, and necessarily unsatisfactory to both attendant and consultant. The rights of the practitioner to his practice should be conserved, so that he should not be put in the position of a mere directory of what specialist or what operator to apply to. The way to effect this legitimately and openly is by means of joint treatment, the routine measures being carried out by the attendant, while direction and supervision are exercised by the consultant. A joint fee bill is suggested as the logical concomitant.

The Vaccine Treatment of "Colds."—G. H. Sherman distinguishes two classes of cases suffering from colds; those having acute attacks that clear up during the intervals, and those in which the condition has a tendency to linger on between the attacks. The former are more particularly due to the pneumococcus and streptococcus, while the latter, in addition, are usually complicated with the *Micrococcus catarrhalis* or the mucous group of organisms. In the treatment of these cases the author uses a mixed stock vaccine composed of various strains of each organism in the vaccine; in the former class of cases pneumococcus 40,000,000, streptococcus 30,000,000, and staphylococcus 150,000,000; and in the latter, pneumococcus 40,000,000, streptococcus 30,000,000 and *Micrococcus catarrhalis*, 100,000,000. Usually there is marked improvement from twelve to twenty-four hours after the first inoculation, and often all the acute symptoms subside and the patient goes on to recovery. On the second day another dose should be given, or the case is liable to relapse, and after that inoculations should be made at from three to six day intervals until all symptoms of the disease have subsided. Those that are complicated with the *Micrococcus catarrhalis* usually require treatment for a longer time than the other class of cases. In some cases it is necessary to double the dose. If prompt improvement should not take place with this routine method of treatment, careful bacterial examinations should be made of the sputum by slides and by culture methods to determine what additional organism may be the cause of the trouble.

Sarcoma of the Testicle.—A. C. Stokes states that typical sarcoma of the testicle occurs more rarely than atypical. Tumors of the sarcoma type, but atypical, occur more frequently than those of the carcinoma type. Typical carcinoma of the testicle occurs occasionally, but always arises in the epididymis or tubules and never in the rete testis. All tumors taking on a carcinomatous appearance are teratomata in origin with the epiblast predominating. The mixed tumors of the testicle originate in the rete testis in tissue which, according to Grawitz, has its beginnings in primitive kidney embryonal tissue of mesoblastic origin carried down in the descent of the testicle. According to Waldeyer, they originate in the sexual cell, which has been subjected to some form of irritation. This last theory agrees more clearly with the clinical picture than does the theory of Grawitz. All organs in which the peculiar tumors develop have the same embryological origin and are derived from the nephros.

The Colon Bacillus.—By R. T. Morris. (See MEDICAL RECORD, January 13, 1912, page 88.)

Salvarsan in Syphilis.—H. J. Nichols points out the difference between salvarsan and mercury as to their action on the spirochetes. With mercury the spirochetes are not killed *en masse*, but a great number are simply repressed and the natural defenses of the body are gradually brought to bear against the infection, and the patient goes more or less definitely through the various stages of the disease as if untreated. Even if he relapses he has the defensive asset in the mercury he has taken already. With salvarsan the case is different—the great bulk of the spirochetes are killed at once and those that remain are too few to stimulate the resistance of the body and they begin again to multiply. Salvarsan has entirely upset the ordinary course of syphilis and has introduced entirely new factors in the possibilities of serious relapse. Hence the advantages of the combination method. While the immediate effects of the salvarsan can be taken advantage of, one can use the other drug, which is able to kill the few remaining spirochetes by its superior penetrating power, and have a powerful combination against relapse. In the primary stage, after diagnosis by the dark-field microscope, the author would excise the lesion if possible, give an intravenous injection of from 0.4 to 0.6 gram of salvarsan and follow this by one month's treatment with mercury by inunction or injection. He would then complete the treatment by a second intravenous injection of salvarsan. If the serum reaction is present at the start a second month's treatment with mercury should follow the second injection. In the secondary and tertiary stages one or more intravenous injections, with a week's interval, should be given until the symptoms are under control, and at the same time an intensive treatment with mercury should be given for one month to six weeks. Then the entire procedure should be repeated, the amount of salvarsan to be given being gauged by the serum reaction. The author has had no bad effects from the use of salvarsan and sees no reason why it may not be employed, using proper precautions, as freely as thymol or any other powerful remedy. While it has not fulfilled all expectations, the day of modern achievements is still young, and the whole history of the practical use of the drug covers only two years, the intravenous method is only about a year old and the various combination methods even less.

Hepatoptosis and Hepatopexy.—A Werelius states that hepatoptosis may be congenital or acquired, the former being attributed to the absence of suspensory ligaments and other defects of the natural supports. Heavy lifting, a pendulous abdomen, gall-bladder disease, and pregnancy are mentioned as factors of the acquired condition. The disease is much more frequent in the female and very few cases occur in nulliparæ. The author has found

only sixty-six cases reported as operated on, and only four of these in this country, including his own. These are tabulated and analyzed as follows: Two were males. The average age of the patients was 38 years. There were twenty-eight cases of total and thirty-eight of partial hepatoptosis. In the partial hepatoptosis the diagnosis was made correctly in twenty-three cases. The condition was once diagnosed as tumor of the gall-bladder, six times as right nephroptosis, and an uncertain diagnosis was made in eight cases. In the total prolapses a correct diagnosis was made in thirteen cases. Incorrect diagnosis of echinococcus cyst was made in four cases, of tuberculous typhlitis in one case, of omental tumor in one case, of right nephroptosis in three cases, and kidney tumor in one case, and an uncertain diagnosis was made in five cases.

Rheumatic Carditis.—W. Lintz reaches the following conclusions: Rheumatism is a specific infectious disease caused by the *Diplococcus rheumaticus*, and has a characteristic pathology. The valvular lesions are caused by the dissemination of the microorganisms by means of the coronary vessels. The murmur heard at the apex, even early in the disease, is never functional, but is due to a loss of tonicity in the mitral sphincter. General cardiac dilatation is to be attributed to the loss of tonicity of the heart muscle. A derangement of the pulse and temperature ratio is of diagnostic importance. A rise of temperature is accompanied by an improvement in the feeling of well-being. Simple and malignant endocarditis represent different degrees of the same process.

Phenolsulphonephthalein Test.—M. L. Boyd reviews the various functional tests for the kidneys and gives his experience with them and with the use of phenosulphonephthalein. Up to the time of the introduction of the latter drug there was no single test by the use of which one could gain any accurate idea of the functional capacity of the kidneys. By the use of various tests one could reach valuable conclusions, which, however, were not always accurate, and failed entirely in certain pathological conditions. The length of time required for some of the tests and the extent of the observations with others made their general use impracticable. Phenolsulphonephthalein is a nontoxic substance rapidly appearing in the urine and harmlessly eliminated through the kidneys, while the amount passed is accurately, rapidly, and easily determined by the colorimeter. The patient is less inconvenienced and the amount of dye eliminated shows accurately the extent of kidney impairment. There is, moreover, no pathological condition of the kidney in which there is increased permeability to the drug and the amount passed does not depend on the quantity of urine. By ureteral catheterization the condition of separate kidneys can be ascertained.

Acetonuria and Acid Intoxication.—B. W. Rhamy states that subcutaneously injected, acetone has a slow cumulative toxic power which may, during periods of individual susceptibility, effect serious or even fatal damage. Subcutaneously injected, the toxic power of acetone is much greater than that of methyl alcohol. Guinea-pigs not only have an individual susceptibility, but have daily variations in their individual susceptibility. Acetone dehydrates and hardens tissue, is a local irritant, and causes hemorrhagic extravasations. If acetone is formed in the intestine or liver it must be in a pure strong state at the site of formation and would there exert its destructive action on the neighboring cells. Following a toxic dose of pure acetone, guinea-pigs develop coma, rapid respiration and nervous phenomena, including itching, dizziness, muscular twitching, and temporary mental disturbance, and may develop convulsions in the form of rapid clonic spasms. The acetone is excreted almost entirely by the lungs. Post-mortem examinations of guinea-pigs killed by acetone poisoning show fatty degeneration of the liver and kidney, with hardened and ruptured blood vessels and hemorrhagic extravasations. Acetone is to be considered a far more important diagnostic sign of toxemia in pregnancy than urea or albumin and should always be looked for as a premonitory danger signal of toxemia.

The Lancet.

February 24, 1912

Glycosuria.—A. E. Garrod classifies the causes of glycosuria as follows: Toxic: administration of morphine, atropine, strychnine, curare, amyl nitrite, copaiba, phosphorus, bichloride of mercury, uranium salts, phloridzin, acetone, chloroform, ether, nitrous ether; poisoning by coal gas, carbon monoxide; alcohol, especially in champagne, and beer; thyroid extract, adrenaline. Asphyxia: accumulation of carbon dioxide in respired air. Cold immersion (e.g., attempted suicide by drowning). Inanition (vagabond glycosuria). Psychic strain or shock. Diseases of the nervous system: Apoplexy, convulsions, traumatism, cerebral tumors, meningitis (meningococcal and tuberculous), syphilitic affections of the brain, general paralysis of the insane, paralysis agitans, tabes. Acute fevers: pneumonia, scarlet fever, measles, mumps, variola, malarial fevers, phlegmonous diseases. Diseases of the liver: cirrhosis, cholelithiasis. Diseases of the pancreas: hemorrhagic pancreatitis, necrosis, carcinoma, fibrosis, pancreatitis of mumps, catarrhal pancreatitis. Intestinal disorders: corrosive poisoning, enteritis, colitis. Diseases of the thyroid gland: exophthalmic goiter, myxedema. Diseases of the pituitary body: Acromegaly, gigantism. Pregnancy, tumors of the uterus, and ovaries. Renal affections: functional and organic. Chyluria.

Treatment of Exophthalmic Goiter.—G. R. Murray advocates operation in all cases where there is distinct stridor from compression of the trachea or persistent pain in the goiter. In cases of a mild type he does not consider an operation necessary. In very severe cases with marked cardiac failure the risk is too great. In a certain number of cases of moderate severity in which no adequate improvement has resulted from medical treatment fully tried for twelve months, a partial thyroidectomy or ligature of the superior thyroid arteries may be advised. The remarkably small mortality from operation clearly indicates that the grave dangers which formerly made physicians unwilling to advise operation have now been considerably reduced, so that operation can be recommended in a larger number of cases than previously appeared to be advisable.

Cystitis.—D. Newman states that in this condition there are three modes of infection: (1) Ascending infection by the path of the urethra, which for obvious reasons is more common in women than in men; for example, in gonorrheal and colon bacillus infection. (2) Descending infection or hematogenous infection, in which the organisms are conveyed from a primary focus to the urinary tract by the blood and are excreted by the kidney. This happens in tuberculous, in typhoid, and in colon bacillus infections. (3) Transparietal infection through the lymphatics from the intestine to the bladder, as observed in appendicitis, dysentery, and internal hemorrhoids. The colon bacillus is the most common cause of cystitis. It is seldom that the bladder is the first part of the urinary tract attacked by the tubercle bacillus, but primary vesical tuberculosis is occasionally met with. Other organisms causative of cystitis are the streptococcus, the pneumococcus, the *Staphylococcus pyogenes aureus*, the *Staphylococcus pyogenes albus*, and the gonococcus. Cystitis may be mild,

severe, or chronic. Juvenile incontinence or involuntary nocturnal micturition in children and adolescents is frequently due to a mild infection of the bladder by colon bacilli. The cystitis of pregnancy, usually met with about the sixth month, is moderately acute as a rule, but is sometimes severe. In the severe type of cystitis the symptoms are constitutional and local. The most important symptom is vesical tenesmus. Chronic catarrh of the bladder is often the result of some blockage to the escape of the urine.

The Intestinal Flora.—A. Distaso believes that constipation and the resulting intoxication are frequently caused by the intestinal flora; and that the large intestine is the seat of these processes. The products of the intestinal bacteria, by increasing secretions inhibiting the submucous plexuses, give rise to stasis. The accumulation of feces in the colon causes the viscera to fall downward, dragging on the organs which are attached to them. The ileum especially is affected, so that it may be almost occluded, or the ileocecal valve may become inflamed, and thus the passage of feces may be further impeded.

British Medical Journal.

February 24, 1912.

Immunity and Organic Evolution.—C. J. Bond states that the assumption of new characters on the part of any individual cell or group of cells is in every case the outcome of variation and selection among units of a certain order, size, and complexity. There are two ways in which the organism adapts itself to environmental changes: by intercellular or by intracellular variation and selection. As an example of the former is cited the phenomenon of muscle hypertrophy resulting from increased use of a muscle, in which case there is the formation of new cells in response to extra effort. An example of intracellular variation is seen in the case of the nerve cell which responds to quantitative and qualitative alterations in the stimuli, thus manifesting what is designated as a typical "use acquirement," the result of adaptation on the part of individual cells to altered environmental conditions. The immunity reaction which may be compared with this type of neural reaction falls as a whole into two great divisions: the natural immunity, which comes about through the selection of more resistant individuals during racial experience of disease, and the acquired immunity, which results from the exercise of an innate capacity of recovery after individual experience of disease; just as the response of the central nervous system is made up of two primary divisions—the racially-acquired innate method of reflex and instinctive action and the individually acquired ideovolitional mode of response.

Operations for Acute Appendicitis.—A. H. Burgess presents an analysis of 500 consecutive operations for acute appendicitis, that is, operations undertaken in the *acute* stage of the disease. There were 285 males and 215 females. The average age was 26.3 years. A history of previous attacks was given by 28.4 per cent. There were 40 deaths, a mortality of 8 per cent. There was a progressive increase of mortality with each successive day of the disease up to the sixth day. Fecal concretions were found in 21 per cent. of the cases. Further improvement in the mortality statistics of operation in the acute stage of appendicitis is to be looked for chiefly upon the lines of earlier diagnosis and of a more general recognition of the advantages of early operation. The early symptoms in their characteristic order of onset are abdominal pain, usually referred at first to the umbilical area and later to the right iliac fossa; nausea and in many cases vomiting; localized tenderness; localized muscular rigidity; and rise of temperature and rise of the pulse-rate. This order of symptoms was first pointed out by Murphy. The fourth symptom muscular rigidity need not be waited for to complete the diagnosis since it indicates that the infection has already spread from the appendix. Vomiting is relatively more frequent in children than in adults. Local tenderness should be searched for not only through the abdominal wall, but also by rectal examination.

Atropine and Open Ether Administration.—H. B. Gardner notes the advantages of this combination as follows: A smooth induction period of six to eight minutes; very early clouding of the mental faculties; tranquil regular respiration with abdominal relaxation; absence of mucus in the air passages; no unusual oozing of blood from the wound; extraordinary safety, alterations in the patient's position or disturbances of vital structures producing barely any depression; maintenance of normal blood pressure and absence of shock owing to the obtundent effects of both atropine and ether; suitability for goiter operations and adenoid and tonsil extirpation; the patient may be safely propped upright on pillows on return to bed; no after-effects, vomiting being quite rare; acidosis improbable; and an unusual value in septic conditions and those with flagging circulation.

Transmission of Leprosy.—H. Bayon concludes from his experiments that leprosy can under certain circumstances be transmitted to animals, the main difficulties being the high percentage of failures and the long incubation. The most suitable animals appear to be the rabbit, rat, or mouse. In the rabbit the intraocular method is preferable. The resulting lesions are often not visible to the naked eye, and are similar to those caused by certain strains of human tubercle. In the rat the incubation is also very long, the resulting lesions being comparable to those occurring in spontaneous leprosy of the rat. Not all leprous patients' nodules are equally infective for animals. In some cases the lepra bacilli appear to be absolutely incapable of multiplication for reasons at present unknown. According to Stanziale's experiments, the Wassermann reaction is positive in rabbits which have been successfully inoculated.

Berliner klinische Wochenschrift.

February 19, 1912.

Priority as to Peroral Auscultation.—Remouchamps of Belgium, in discussing Takata's recent description of peroral auscultation as devised by him in 1907 and since then notably developed, states that he introduced this resource independently in 1903, and that he in turn was preceded many years by Prof. Galvagni of Modena. In 1875 the latter reported the method in an Italian journal and to insure its accessibility to the scientific world he also caused it to be published in a German periodical. After the publication of the present author's article in the *Semaine Médicale*, in 1903 Genairon made buccal auscultation the subject of a graduation thesis (Lyon, 1904). Prof. Galvagni gave the subject a systematic consideration, while Remouchamps was interested chiefly in a laryngeal sound heard through the mouth, which he termed laryngeal crepitation and brought in relation with incipient consumption.

The E. T. Urine Reaction.—Under this designation von Balazsy gives a brief bibliographic résumé of the so-called Engel-Turner reaction, employed by the author in

determining qualitatively the chlorides in nurslings' urine. At present he has studied the urine of over 300 nurslings from this viewpoint. If the dietetic chlorides are diminished an increased elimination of chlorides occurs for some days; while if the amount ingested is increased, chloride retention results. As a rule breast-fed children give a positive, bottle-fed children a negative reaction. In making the test the urine is titrated with a solution of nitrate of silver, to which is added a little potassium monochromate. As soon as the urinary chlorides have combined with the silver an orange yellow color appears (silver monochromate).

The Psychic Component in the Asthma Cause Nexus.—Sänger calls attention to the great diversity of conditions under which asthmatic attacks occur and enumerates body overexertion, sneezing, coughing, laughing, gastroenteric disturbance, menstrual disorders, residence in a particular locality, whether town, residence quarter, or even room, certain odors, certain combinations of weather conditions, etc. The factors which precipitate asthmatic paroxysms may be equally potent in arresting and preventing them, a fact which must be well borne in mind by the practitioner. Dancing is with some individuals a favorite prescription for themselves or others. The psychic component is very apparent in an affection of this character—its suggestible causation and suggestible cure. In other words, the predominant notion in therapy is that of diverting the asthmatic's attention.

Exclusion of the Bladder in Vesical Tuberculosis.—Casper states that as far as he is aware this intervention has been practiced but twice before. He increases the material by two additional cases. This small number of cases comes about because there is seldom an indication, not because it is so formidable. The bladder often heals spontaneously after a tuberculous kidney is extirpated. The true indication is present only in cases of extreme contraction of the organ, with extreme painfulness, so that not only has it become worthless for its purpose, but is a source of great suffering. Of two patients thus treated, one died from the operation. He had been nephrectomized, and the operation was followed by anuria. The other patient recovered and the case may be given in some detail. The patient had been nephrectomized and the remaining kidney had since become tuberculous. An incision was made upon the kidney, which was normal to sight, and a lumbar urinary fistula was established. The ureter was not being employed in the latter, for its central end was split and sutured directly to the skin. The vesical pains at once ceased. There was no tendency to anuria. The patient made a relative recovery, gained twelve pounds, and will doubtless improve further. He wears a urinal, but owing to mechanical difficulties its action leaves something to be desired.

Münchener medizinische Wochenschrift.

February 20, 1912.

New Symptom of Acute Salpingitis.—Kuhl claims to have noticed frequently that a beginning salpingitis differs from a parametritic abscess, an acute appendicitis, etc., in having the febrile acme associated with bradycardia. This being admitted, the only possible explanation is found he believes in the absorption from the inflamed focus of some substance capable of acting upon the vagus. The same phenomenon has long been known in cases of biliary infection, but there is not much likelihood of confusing the latter with salpingitis. The author hopes that his supposed discovery will be verified as the result of an investigation of the subject at one or more of the large gynecological clinics.

Heredity and Heart Disease.—Herz quotes the prevalent belief in the noninheritance of cardiac disease, which he feels justified in opposing. He knows of no available statistical material, but in his capacity as a specialist in cardiac complaints has seen a sort of familial association of rheumatism (endocarditis, etc.), cardiac neuroses, and arteriosclerosis. All three of these elements are in themselves hereditary and familial when separately considered, and might conceivably exist side by side. Each is capable of giving use to cardiac lesions or symptoms. Phrenocardia, or psychogenous disturbance of the heart which may be transmitted to one's descendants, is also at times an occasion of so-called psychic infection or unconscious imitation. The association of rheumatism, heart disease, and chorea in the same family is well known. Hence there is readily conceivable an indirect inheritance of cardiac troubles, that is, an inheritance of troubles which are from their very nature associated in some way with cardiac symptoms.

Postanginal Polyarthritis.—Roethlisberger discusses this somewhat uncommon sequence which is believed to be only a chance episode in the absorption by the tonsils of some weakly septic organism. He describes two cases and concludes that in all rheumatism, acute or chronic, the tonsils must invariably be investigated. We may see an acute tonsillitis followed by a chronic rheumatism and vice versa. The anterior and posterior tonsillar recesses, as well as the crypts, should be examined with great care and the contents of the latter expressed. Diseased tonsils should be removed if medical management is inefficacious. So-called massage of those structures is often sufficient to reduce them to normal size, consistency, etc.

Deutsche medizinische Wochenschrift.

February 15 *and* 22, 1912.

Treatment of Trigeminal Neuralgia with Schlösser's Deep Alcohol Injections.—Dollinger concludes that in this resource we possess a means of arresting a facial neuralgia and of producing a relative cure which may persist for a long time. In most cases the condition returns in from one to five months, but not in as severe a degree. The treatment is able to affect favorably the recurrence, some times in a much higher degree than at first. From this point of view the treatment may be regarded as furnishing eventually a radical cure. The results from Schlösser's method are considerably better than those which follow section and resection of the nerves; so that in a severe case of facial neuralgia we must choose between Schlösser's method and gasserectomy or extraction of nerve roots respectively. The latter are certain cures, but the intervention is formidable. The author has not done a ganglion extirpation since he began to use the injections, which shows incidentally that patients naturally choose the less severe method. Too much weight, however, cannot be ascribed to this experience, for cases will always occur in which the radical method must obtain. For example, a military officer on active duty, if tormented and rendered inefficient by a facial nueralgia could not afford the time required for an injection cure, which would amount to at least three months.

Natural Immunity and Specific Antisera.—Seiffert mentions the natural property of normal blood serum to inhibit bacterial growth and believes that natural and individual immunity are based on this property. Experiment shows that it is effective against numerous disease germs. But serum does not behave always alike under these circumstances, and, in fact, two distinct groups of microorganisms may be differentiated from this viewpoint. Thus if the serum destroys a bacillus which liberates endotoxins after death this is the very reverse of a protective asset. The really immune subject here is the one whose serum does not antagonize the proliferation of such germs provided the latter do not cause septicemic

phenomena. On the other hand, the great group of septic infectious diseases is antagonized when the serum destroys bacteria *in situ*. There is possibly a third group which comprises the pure toxicoses in which bacteria do not tend to enter the blood at all. The author does not as yet make a familiar application of these teachings to clinical medicine.

Traumatic Appendicitis.—Brüning defends his conception of this affection against the scepticism of Sprengel. The latter, he believes, stands pretty much alone in the narrowness of his views, since men not less than himself in authority recognize a distinct traumatic type of this affection. There is naturally room for differences of opinion as to whether or not a perfectly healthy appendix ever becomes inflamed as the result of direct violence, but the whole subject of appendicitis is involved in this question. The problem cannot be settled by citing one or more cases of supposed traumatic appendicitis which were found on operation to represent ordinary cases with no superadded evidence of traumatism.

Toxicity of Methyl Alcohol.—Harnack believes that the Berlin poisonings were a sort of blessing in disguise since they served to attract universal attention to the subject of pure and falsified drinking spirits. The toxicity of alcohols in general increases with the number of carbon atoms in the molecule, so that merely considered as an alcohol, ordinary grain spirits should be considerably more toxic than wood spirits. But ethyl alcohol is combustible in the organism, while methyl alcohol is incombustible, so that the latter actually has the higher toxicity. Methyl alcohol is indeed slowly oxidized to formic acid, and if alcohol behaved in the same manner it would be slowly burned to acetic aldehyde and acetic acid. As a matter of fact, however, it is quickly oxidized to CO_2 and water, so that it is comparable with sugar in this respect. When in the chronic consumer of ordinary alcohol the ability of the organism to oxidize it becomes forfeited toxic phenomena promptly appear. The ability of the individual to oxidize methyl alcohol to formic acid undoubtedly varies. Harnack appears to believe that methylism is really formic acid poisoning, and it follows that when methyl alcohol is taken with relative impunity, which often occurs, there is deficient oxidation. Formic acid is the only one of its series which is at once an acid and an aldehyde, and on this property its high toxicity appears to depend. If the formic acid action can be eliminated, methyl alcohol is toxic only as an alcohol, and hence less toxic than ethyl alcohol. All the alcohols appear to be neurotropic and neurotoxic, due, perhaps, to the fact that they are lipoid dissolving agents, and this property increases with the number of carbon atoms as already stated. But the special toxicity of wood alcohol to the optic nerve act must rest on some peculiarity of oxidation in these tissues.

The Combined Operation in Cancer of the Rectum.—Riese writes at length on this subject. Six years ago Kraske abandoned his original radical sacral procedure for the combined method, and for the past few years we have not been hearing very much about results in this field. The very high operative mortality from this sort of intervention is not improving and a death rate of nearly 50 per cent. in some series in an operation apparently incapable of further technical development is not likely to be made the occasion for publication of material. The author, despite an operative mortality of 45 per cent., lost only one of his last seven patients, which encourages him to report his cases. Naturally, if this ratio or anything like it could be maintained, the results would compare very favorably with the latest results in Wertheim's radical operation for cancer of the uterus. Moskovicz has a recent series of sixteen cases with four deaths. It is too soon to compute any results for the combined operation in Germany. Rotter, the oldest operator by this method, has one patient living and well seven years after operation and two who have passed the three-year limit. Hochenegg and half a dozen other operators are still doing the old Kraske operation, and the first named has accumulated a great material, but aside from some ten men who do either the old or more recent operation the German surgeons do not care to use radical methods for rectal cancer. In other countries the radical operators are the Mayos in America, and a few French, Swiss, and Japanese surgeons. The problem becomes quite different, however, if we look upon it not so much as a systematic attempt at radical cure, but as suited to prolong life for a certain time and make life endurable. Hence whenever a cancer by reason of its seat cannot be removed from below, whenever it is practically a cancer of the colon, and in other conceivable conditions it may be justifiable in particular cases to operate from above and behind the growth by the combined method. The author has operated only eleven times by this resource, which is, of course, a very different procedure from the routine sacral operation as done so extensively by Kraske and Hochenegg.

The Large Flaccid Abdomen in Infants.—A. B. Marfan distinguishes two types of large abdomen that are found in nursing infants; the tympanitic, which is hard, distended, and sonorous on percussion, and the relaxed, which is soft, depressible and dull on percussion. The tympanitic abdomen is preceded or accompanied by diarrhea or severe constipation. The flaccid abdomen is accompanied by anorexia and dyspeptic symptoms that are not marked. The walls are thinned and atonic, and eventrations are seen between the recti and the lateral abdominal muscles. Measurements of the intestines have shown that they are much elongated and the walls thinned and atonic. It is this elongation and increase in size of the bowels that causes stretching of the atonic abdominal muscles. The condition occurs generally with the symptoms and deformities of rickets, and the author believes that the same causes that bring about rickets are responsible for this type of enlarged abdomen.—*Archives de Médecine des Enfants.*

Little's Disease.—V. Hutinel and L. Babonneix state that Little's disease is a congenital condition the causation of which is not well understood. Inasmuch as the disease appears immediately after birth and is essentially chronic there have been few autopsies, and these have been performed when the patient reached a late stage of childhood or even adult life. Hence the pathology and physiology are not well understood. The disease manifests itself in a condition of stiffness of the muscles, contracture, slight mental changes, convulsions, etc. It is especially frequent among premature children. It seems generally to be caused by the operation of several factors. These are mainly of a toxic, infectious or mechanical nature, in the last case arising from injuries at birth. The toxic and infectious causes may be operative before conception, as in syphilis; in the mother during pregnancy, as in alcoholism, and in the fetus before or after birth. Emotional causes have probably no real agency in the production of the disease. Infectious diseases and digestive disturbances in early life increase the already present failure of nutrition. All of these causes operate through the nervous tissues, the lesions being those of blood-vessel change, hemorrhage, and sclerosis. Complicated labor, premature labor, and asphyxia are given as causative factors. As to pathology there are always cerebral alterations about the upper Rolandic area and in the pyramidal tracts which differ in no way from those present in other varieties of cerebral paralysis. —*Annales de Médecine et Chirurgie Infantiles.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

FIGURE.—An applicant may be erect, vigorous, muscular, and compact, or, on the other hand, he may be so stooped, frail, thin, emaciated, fat, or deformed that he is not entitled to life insurance. If, however, the applicant is thin, but still healthy and wiry, or if he is an overweight but muscular and with fat evenly distributed, or if he is stooped from the habit of carrying himself in that way or as a result of his occupation, these modifying facts should be clearly described in the medical report.

GENERAL APPEARANCE.—The general appearance of a man is an important matter and a close, keen inspection may enable the examiner to recognize slight signs of existing physical weakness, previously unsuspected. Examiners of considerable experience and observation place due confidence in the conclusions deduced from a careful survey of the general aspect of the applicant, and though they may be at a loss at times to give an adequate reason, their impressions, nevertheless, are entitled to respect. In other words, a case is occasionally encountered in which the appearance indicates more or less ill health and yet it is difficult or impossible to locate the focus of the disturbance, no matter how carefully and rigidly the examination is made. Under such circumstances the examiner is justified in recommending rejection or postponement on the ground that the unfavorable appearance is the result of some obscure or latent disease.

The condition known as a "healthy appearance" cannot be defined clearly, for while it is evident to all that a strong vitality and a robust constitution is usually indicated by the complexion and tone of the tissues, there are several grades of appearance between that of the clean-cut, robust individual with an abundance of muscle and one who is uninsurable on account of the presence of any earmarks of disease. A company which limited its business to athletes and risks first class in every respect would find its field very limited and needlessly so, as applicants of this kind have no better longevity as a class, other things being equal, than those of average health and who, perhaps, are sedentary in their habits to a moderate degree and consequently without much muscular development or signs of unusual vigor.

The salient points to be observed in estimating the quality of the risk from the general appearance are described in the following paragraphs:

The Term "Fair."—The use of the term "fair" is strongly condemned: it should never be employed in reference to the general appearance or in any other part of the medical report. It is too elastic and ambiguous and has no decided significance except to the one who uses it, and he will therefore always be requested to explain his understanding of the word as it applies to the individual case through further correspondence. The examiner has the advantage of inspecting the applicant personally, and he is expected to determine whether the risk is acceptable or not and, further, to express his opinion in a way that will leave no doubt at the home office. If the examiner cannot form a definite conclusion, the medical directors who must judge the case entirely on paper will be in a poor position to do so.

Pallor.—When the applicant is noticeably pale, ascertain whether it is due merely to indoor occupation or an inherited complexion, or to anemia or some other disease, and be sure to report the findings explicitly.

Whenever the word "pale" is used in the report, the cause should be given at the same time, as the pallor may or may not be significant.

A pale face with dark rings under the eyes may simply be an indication for a needed rest and change of air. If, however, the pallor is accompanied by a tired look, a dull skin, a gray drawn countenance, and gray hair, it may denote that continued hard work and worry have brought on premature old age and should prompt the examiner to make a search for thickening or hardening of the arteries. In either event, the pallor should be reported and the cause clearly described.

Plethoric Appearance.—Do not make the mistake of judging that the fresh complexion or even a full, flushed face is always due to plethora. Exposure to air will cause this even to the extent of dilated capillaries. On the other hand, it is true that the dilated capillaries may arise from high living with too much food and wine. In the latter class the examiner should consider the matter carefully before referring to the condition as one of "apoplectic tendency" unless it is sufficiently well marked.

It should always be remembered that some of those addicted to the excessive use of alcohol have very little color as a result—in fact, they may have a full, flabby, pale face, but they are also apt to have puffiness under the eyelids, a glassy, watery eye, and a dull, nervous expression. Acne rosacea, though frequently associated with excessive alcoholic habits, is also common in digestive disorders and during the menopause in women.

Jaundice or Sallowness.—Either of these conditions should lead the examiner to inquire as to whether there is any history, past or present, of gastrointestinal disorders or gall-bladder troubles, and the result should be clearly stated in the report.

General Build.—Observe whether the applicant is muscular, thin, corpulent, or flabby. If he is an overweight, state if there is any excessive accumulation of fat on the abdomen.

APPARENT AGE.—A man's prospects of life are not gauged by his age in years, but rather by the actual age of his tissues which is usually shown by the general appearance and by the condition of his arteries. Some people are relatively older at 45 than others at 55 or 60, the decline of life beginning at periods which vary with the amount of inherited or acquired vigor of the individual. Premature senility is a distinctly unfavorable feature and a condition which will probably be encountered more often in the future than in past years on account of increasing business and social stress with the attendant degenerative changes. When there is a marked discrepancy between the given and apparent ages, it should be reported. A difference of a comparatively few years, however, may be due to an unkempt appearance, the same individual looking considerably younger after a visit to the barber and the wash basin. Furthermore, in doubtful cases, where the discrepancy is a slight one, there would be quite a difference in opinion among several observers as to whether or not the applicant looks older than the given age.

Another question arising when the applicant looks older than the given age is whether or not

he has given a younger age than the true one in order to obtain a policy with a lower premium rate than he is entitled to.

RACE.—Do not confuse race with nationality in answering this question. It is a common error to state that the applicant is "American," the examiner seeming to forget that this answer does not convey the information to the company as to whether the proposer is a white, negro, mulatto, or Indian.

The Texas Association of Medical Directors.—At a meeting of this association held in San Antonio, February 20, 1912, the following officers were elected: *President*, Dr. John S. Turner, Dallas; *Vice-President*, Dr. Whitfield Harral, Dallas; *Secretary* and *Treasurer*, Dr. M. M. Smith, Dallas. It was decided that all of the officers should be residents of the same town, in order to facilitate frequent conferences. The association discussed many insurance topics of great interest and adjourned to hold its next meeting during the session of the Texas State Medical Association at Waco, in May, 1912.

Injury, Paresis, and Life Insurance.—Sir George H. Savage states that recently a very practical point has arisen in relationship to the part that injury may play in the production of general paralysis. In questions of compensation for injuries leading to death and also in cases of life insurance it may be contended that injury alone would not have caused the disease. The great majority of authorities look upon general paralysis and locomotor ataxia as almost certainly associated with, if not fully resulting from, syphilis. Yet the author finds that even such an authority as F. W. Mott hesitates when asked if it is impossible for general paralysis to arise from accident alone. Both observers agree that in a very large majority of cases of general paralysis syphilis of long standing can be established, but that this disease alone is not the only factor.

The question of heredity comes in, just as with alcoholic poisoning certain persons suffer in their brains while others do so in their general viscera, so with syphilis; in some the stress of the disease falls upon the nerve centers, while in others it selects other parts such as the skin or the bones. Though syphilis is most commonly associated with general paralysis, yet it requires other elements to start the disease. The author believes that a meat diet and alcohol are factors in many cases. Syphilis seems to ripen the brain for decay, and any accident from within or from without may lead to decay. The following illustrative case is mentioned: A man, who many years before had syphilis, was properly treated, and has been a healthy man, receives a blow on his head, which renders him insensible. He may recover from this, but within a few months some alteration is noticed in his conduct. If in the army or navy he gets into trouble by faults of irregularity or unpunctuality. He is irritable and forgetful; slowly the other signs of general paralysis appear and he is invalided. A claim is now made for disability depending on accident. Without the previous syphilis he would not have developed general paralysis, but without the accident he might never have developed it, or, at any rate, not for years.

In the author's opinion the man ought to be treated as if the accident were the efficient cause of disablement. In the same way in cases in which it is a question of life insurance, it is presumed that a man who has had syphilis would have some addition made to his premium, but if he is following a life which is more than usually associated with risk of even slight accidents, such as being in the army or navy, the author believes a good deal ought to be added. He knows of no cases which have actually arisen in relationship to these points, but there have arisen cases in which pension questions had to be considered.—*Lancet*, February 3, 1912.

Injuries of the Spleen and Their Consequences.—Knepper says that the spleen, because of its smaller size and well protected situation, is not as exposed to injury as the liver. Lately, however, injuries of the spleen have assumed an important position in accident insurance because of the possible relation between leucemia and trauma of the spleen. Usually because of its relations to the diaphragm, left kidney, lung, intestines, and stomach, the spleen is seldom injured alone. Being completely covered with peritoneum, injuries of the spleen mean serious peritoneal complications; moreover, because of its small size, there is always a possibility of a prolapse of the spleen through an external abdominal wound.

Penetrating wounds of the spleen are no longer looked upon as necessarily fatal, surgeons having learned to stop the considerable resulting hemorrhage by packing, ligating, etc. Moreover, it has been shown that parts of the organ may be removed without compromising the vitality of the remainder. It is still undecided whether a healthy spleen may be injured by indirect force resulting from a fall, blow, etc. If the organ has been changed by disease, such as typhoid fever, malaria, hepatic cirrhosis, etc., very light violence is sufficient to injure it. Rupture of the organ has in such cases followed coughing, sneezing, quick turning of the body, etc. Spontaneous rupture may occur in malaria.

A diagnosis of subcutaneous injury of the spleen must be made on the signs and symptoms of internal hemorrhage and on pain and tenderness in the splenic region. This pain radiates occasionally to the left shoulder and left arm; this, however, is not such a frequent symptom as the right shoulder pain in injuries of the liver. Occasionally the left hip is likewise painful. Increase of splenic dullness because of injury can but rarely be demonstrated. All these considerations show that the diagnosis of splenic injury is a very difficult one.

The question whether total removal of the spleen is indicated in case conservative treatment of an injury is impossible must nowadays be answered in the affirmative. Krabbel in 1899 collected fourteen cases of extirpation of the spleen, seven patients having recovered. Since then numerous other cases have been published and it is the consensus of surgical opinion that operation is indicated in most cases of splenic injury, and extirpation of the spleen should be performed in every case in which the injury has been so severe as to make it probable that necrosis of the organ will result. Knepper names various references to support this opinion.

Among the consequences of splenic injury, peritonitis from infection or from necrosis of the organ is first to be considered. Localized infection may occur and thus compel a valuation of the amount of injury and the adjudgment of a corresponding indemnity. A wandering spleen may but rarely be accounted for by injury alone; any existing predisposition in this respect, however, may be easily exaggerated by an accident.

The question of the development of leucemia after splenic injury is a most important one and various views are entertained in regard to it. Ebstein says that the possibility of such development has been admitted long before the appearance of accident insurance by such men as Virchow, Mosler, etc. Ponfick has reported a case of leucemia following an injury in which scars following the trauma were discovered at the autopsy. Stern correctly says that we do not yet understand the possible causal relation between trauma and leucemia, but we must not allow an injured person to suffer, because of our ignorance, the loss of an indemnity possibly due him.—*Zeitschrift für Versicherungs Medizin*, December, 1911.

Book Reviews.

A Handbook of Health. By Woods Hutchinson, A.M., M.D. Sometime Professor of Anatomy, University of Iowa; Professor of Comparative Pathology and Methods of Science Teaching, University of Buffalo; Lecturer, London Medical Graduates' College and University of London. Author of "Preventable Diseases," "The Conquest of Consumption," etc. Price $1.25 net. Boston and New York: Houghton Mifflin Company, The Riverside Press, Cambridge, 1911.

The handbook is written in the same trenchant and happy style that has characterized the previous books of this author. The subjects of food and drink, air, skin, muscles, nerves, exercise and growth, the special senses, the speech organs, and the teeth are all lifted out of the ordinary rut of dullness by the writer's fresh and original manner of handling them. Chapters are also devoted to the subject of infections and how to avoid them, and to accidents and emergencies. In his foreword the author summarizes his aim when he speaks of his purpose "to write a little handbook of practical instruction for the running of the human automobile, with just enough description of its machinery to enable a beginner to fuel it, run it, and make roadside repairs." As far as possible the text embodies positive rather than negative suggestions and advice. The volume is copiously illustrated, and its value is enhanced by a full index.

Index-Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Second Series, Vol. XVI. Skinko-Styrants Washington, 1911.

In the report of Lt. Col. Walter D. McCaw, librarian, it is stated that this volume contains 9,890 author titles representing 4,670 volumes and 10,786 pamphlets. It also contains 3,892 subject-titles of separate books and pamphlets and 24,135 titles of articles in periodicals. The Surgeon-General's library now contains 170,690 bound volumes and 315,494 pamphlets.

Consumption, Its Prevention and Treatment. By E. W. Diver, M.D. Second Edition. Price 2/6 net. London: John Bale, Sons & Danielsson, Ltd., 1911.

This little volume, dedicated to the author's colleagues who, in the early days of the fight against tuberculosis, faced with him the peculiar difficulties associated with the introduction of sanatorium treatment into England, is primarily intended for patients who desire to enter the sanatorium and to prepare them for the discipline essential to the successful treatment of tuberculosis. The book describes the various phases of prophylaxis, rest, exercises, food, and recreation in vogue in all well equipped and well conducted sanatoria. It is embellished with a few illustrations, the most interesting of them being of a revolving sleeping chalet. The volume would answer its purpose admirably were it not for the unfortunate tendency of the author to quote and describe cases. Particularly out of place seems to be the citation of a case which ended fatally because the patient did not enter the sanatorium in time. The author insists on having the temperature taken by rectum and by the patient himself. While the taking of the rectal temperature by physicians for diagnostic purposes is of course more accurate and hence more commendable, in this instance the reviewer questions the advisability and the necessity of this procedure as a routine method to be carried out by the patient several times daily. Aside from these little blemishes and the unscientific term of "tubercular" instead of "tuberculous" when referring to a disease due to the bacillus of tuberculosis (an error which the author may remove from future editions), the book is excellent and may safely be handed to the prospective sanatorium patient.

Die Gicht und ihre Therapie. Mit besonderer Berücksichtigung der Diatetik. Von Prof. Dr. A. Schittenhelm, Erlangen, und Privatdozent Dr. J. Schmid, Breslau. Zweite, erweiterte Auflage. Price 1.8 marks. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1911.

This admirable little monograph gives a complete résumé of purin metabolism and its disturbances in gout. Discussion of treatment follows the presentation of the pathology of this disease, dietetic, medicinal and physical therapeutic methods being fully described. Among the latter the use of radium emanation in gout therapy is given much space. The booklet should prove of great interest to American internists, as the medical literature in the English language has not kept up with the progress made in Germany in the study of the etiology, diagnosis, and especially the treatment of gout.

Scientific Features of Modern Medicine. By Frederic S. Lee, Ph. D. Dalton Professor of Physiology, Columbia University. Price $1.50. New York: The Columbia University Press, 1911.

This volume consists of a series of lectures delivered during the past year. These lectures are intended to show how the medical practice of the present day differs from that of the past. The lectures deal with: The normal human body; The nature of disease, and the methods of diagnosing disease; Methods of treating disease; Bacteria and protozoa, and their relation to disease; Treatment and prevention of infectious diseases; The problem of cancer, and other problems; Features of modern surgery; The rôle of experiment in medicine, and the public and the medical profession. It is to be hoped that the educated layman, for whom the lectures were specially designed, will "read, mark, learn, and inwardly digest" the wholesome mental pabulum here supplied by the author. The book is well written, and the language is not too technical.

Thérapeutique Chirurgicale et Chirurgie Journalière. By G. Phocas, Professeur de Clinique Chirurgicale à la Faculté de Médecine d'Athènes; Ancien Professeur Agrégé de la Faculté de Médecine de Lille; et J. Barrozzi, Ancien Interne des Hôpitaux de Paris. Lauréat de la Faculté de Médecine de Paris. Second edition with 630 figures in the text. Price 16 fr. Paris: Vigot Frères, 1912.

The first edition of this work was written by Phocas and appeared in the collection of the "Manuels de Thérapeutique Clinique," edited by Prof. Lemoine of Lille. In the second edition Phocas has had the aid of Barrozzi, the author of the well-known French "Manuel de Gynécologie pratique." The Thérapeutique Chirurgicale forms a companion to the fifth edition of Lemoine's Thérapeutique Médicale et Médecine Journalière.

The second edition is a much more ambitious work, yet the main points which made the first edition so successful have been kept in mind. The authors have set themselves the very difficult task of producing a work on surgical treatment which is within the scope of the ordinary practitioner, and yet is a sound guide to the best modern surgery. Although the book is didactic in nature it appears to mirror the best practice of the day. Its strength is its advocacy and application of sound surgical principles to every day surgery.

The physician wishing to review a surgical point arising in his daily practice can turn to this work and quickly obtain precise information for forming an intelligent opinion. The descriptions of the common operations are clear, concise and accurate; the advice sound and the combination of brevity and accuracy leaves a forcible impression.

The work is divided into three parts; the first part takes up the subjects of sterilization, asepsis, antisepsis, hemostasis, anesthesia, radium, radiotherapy, fulguration, and general surgical technique, including amputations and resections; the second treats of the diseases of the tissues; the third, which forms the greater part of the work, deals with regional surgery. There are 630 illustrations in the text, the majority are diagrammatic in nature and call attention to some principle of treatment. In addition to the usual subject and author indexes there is a helpful alphabetical index.

Clinical Diagnosis. A Manual of Laboratory Methods. By James Campbell Todd, M.D., Professor of Pathology, University of Colorado. Illustrated. Second edition, revised and enlarged. Price $2.25 net. Philadelphia and London: W. B. Saunders Company, 1912.

In this volume will be found a concise statement of the more important laboratory methods, together with an aid to the interpretation of the results. The student and practitioner, as distinguished from the laboratory worker, will find the book of distinct value. Not the least of its services is the indication of the chief methods out of the enormous number provided in the larger books dealing with the subject. Among the additions in the present revision are sections on: The use of artificial light and the importance of numerical aperture in microscopic work; photomicrography with simple apparatus; the antiformin method for tubercle bacilli; detection and significance of albumin in the sputum; Tsuchiya's modification of Esbach's test; the formalin test for ammonia; Benedikt's test for sugar in the urine; volume index of red blood corpuscles; Wright and Kinnicutt's method of counting blood platelets; Harlow's blood stain; a simple technic for diagnosis of typhoid fever by blood cultures; the Wassermann reaction; and Frothingham's method of demonstrating Negri bodies in rabies.

Biological Aspects of Human Problems. By Christian A. Herter. New York: The Macmillan Company, 1911.

A pathetic interest is attached to this work, which was the last one from the pen of the late Dr. Herter, which, indeed, was left in an unfinished state by his untimely death. We are indebted to Susan Dows Herter for her skill in editing the manuscript and in thus preserving for us the seasoned conceptions of life which the profound study of biology had given the author. The scope of this volume is amply indicated by the chapter headings. The subject matter is dealt with in four books. Book I. treats of the animal body as a mechanism, and includes chapters on the mechanistic conception, growth and reproduction, and consciousness and the will. Book II. deals with the self-preservative instinct, under the following chapter headings: the instinct of survival, defences of the body, self-preservation and the mental life, and death and immortality. Book III. treats of the sex instinct, discussing sex and the individual, sex and social relations, and the male and the female mind. Book IV. takes up the fundamental instincts in their relation to human development, and has chapters on the arts and religion, education and the future of the race, and the fruits of education. The philosophy of the author may be discerned in the aim to seek a biological basis for human conduct, but other guides such as those furnished by religion and metaphysics are not pushed aside. This volume is one which may be read with profit by everyone interested in human welfare.

The Control and Eradication of Tuberculosis. A Series of International Studies; by Many Authors. Edited by Halliday G. Sutherland, M.D. Edinburgh and London: William Green & Sons, 1911.

The somewhat pretentious title of this book is apt to prejudice one against it and this prejudice becomes somewhat justified when one realizes the large social aspect of tuberculosis which, in spite of the multiplicity of subjects treated by 32 different contributors, has received but very scant recognition.

The book is primarily intended as a tribute to Dr. R. W. Philip of Edinburgh, the founder of the tuberculosis dispensary system. The Edinburgh system, its principles and methods, are described in chapter 3 by Dr. Sutherland, a pupil of Philip. This system of controlling tuberculosis does not differ from the one in vogue in this country, *i. e.*, the tuberculosis dispensaries known in the City of New York as clinics for pulmonary diseases, sanatoria, the reporting of the disease, hospitals for advanced cases, and farm colonies. To an American reader the description of the construction of a sanatorium without outdoor sleeping devices is somewhat disappointing. Of course, it is possible that the Edinburgh climate does not permit this practice, almost universal in the sanatoria of the United States.

Professor Beranack devotes an interesting chapter to the theoretical and practical basis of tuberculin treatment. Very striking on this subject is his introductory sentence: "In spite of much research during the years that have elapsed since Koch's discovery of tuberculin, we know very little of its chemical composition, of its mode of action, or of the degree of immunity which it confers upon man or upon animal." In his conclusion on tuberculin treatment he is more positive as to its therapeutic value but urges physicians to familiarize themselves most carefully with the method of tuberculin treatment before resorting to it. He limits the use of tuberculin to cases of the first and second stages and uses a product of his own which he claims is less rich in albuminous substances.

Malcolm and Galbraith contribute an interesting article on the physiology of digestion in its application to dieting in tuberculosis. The final paragraph of Mackenzie's contribution on the English method of the administrative control of tuberculosis deserves particular mention, for it deals with the insurance against tuberculosis, and he very pertinently says: "With the National Insurance Bill there enters a new factor in the administrative control of tuberculosis. If this bill becomes law, the acceleration of the growth of administrative control will be enormous, for the bill itself provides new funds, and, incidentally, large grants outside the bill have been promised." According to this bill "there is, first, the sum (estimated at about £1,000,000) formed by the contributions of insured persons. This will be available each year for the appropriate treatment of insured persons alone. Second, there is a building grant of £1,500,000. This is to be distributed by the local government boards of the respective counties in "making grants" for the "provision of sanatoria and other institutions for the treatment of tuberculosis or such other diseases as the Local Government Board with the approval of the Treasury may appoint." The administrative measures for the control of tuberculosis in New York City are described by Dr. Hermann M. Biggs, the originator of them.

In the chapter under Tuberculosis Laboratories, there is found the last contribution of the late Professor Arloing of France, under the title of "Antituberculosis Vaccination of Bovines." The remainder of the book describes the antituberculosis movements in Canada, South Australia, South Africa, India, Germany, Austria, Russia, Italy, Switzerland, the Netherlands, and the Scandinavian countries by representative specialists of those countries. The United States has the distinction of having three other contributors besides Dr. Biggs. Dr. Lawrason Brown describes the antituberculosis movement in the United States in general; Dr. Vincent Y. Bowditch the work in Massachusetts, and Dr. W. Chas. White the work in Pittsburgh.

The last chapters are devoted to the enumeration of Dr. Philip's writings and to reproductions of some of his principal addresses. The reviewer cannot refrain from quoting here what this veteran phthisiotherapeutist has to say in one of them on the value of laboratory tests (opsonic index) as compared with clinical phenomena: "Speaking as a clinician, with prolonged experience in the use of tuberculin, may I say that I am unable to acquiesce in the proposal to replace thorough clinical observation by reference to one set of phenomena, namely, those of the blood." In another address Dr. Philip emphasizes as the key to success in the antituberculosis campaign "the harmonious coordination of all well directed measures."

It is a pity that so valuable a book, comprising 450 pages, should be so lightly and carelessly bound.

Die Ursachen des chronischen Magengeschwürs. Von Dr. J. W. Th. Lichtenbelt. Preis, mark 3. Jena: Gustav Fischer, 1912.

Lichtenbelt first repeated the experiments of Dr. W. van Yzeren. The latter was able to produce chronic gastric ulcers in rabbits by destroying the vagi below the diaphragm. These ulcers were usually found near the pylorus. These experiments were confirmed by Lichtenbelt. In the second part of his monograph the author investigates the interesting question whether narrowing of the pylorus causes the formation of gastric ulcers. It is well known that in cases of ulcer there occurs frequently pylorospasm, causing retention and hyperacidity. This is often followed by hemorrhage. Through his experiments Lichtenbelt was firmly convinced that contractions of the muscular wall of the stomach cause ulceration. The hypertonic condition of the sphincter pylori is, as experience teaches, an important remote cause of ulceration. Thus in rabbits the application of a simple ligature to the pylorus will often cause the development of ulceration. The present monograph on the causes of the chronic gastric ulcer can be warmly recommended.

Clinical Immunity and Serodiagnosis. By A. Wolff-Eisner, M.D., Berlin. Translated by Ray W. Matson, M.D., Professor of Histology, North Pacific College of Dentistry and Pharmacy, Pathologist to Multnomah County Hospital, Physician to Portland Free Tuberculosis Dispensary. Revised and Edited, with a special introduction by the author. Price $2.50 net. New York: William Wood & Company, 1911.

The effort of the clinician to familiarize himself with recent advances in immunity is apt to be hindered by the fact that a large literature is in foreign languages and most of the publications are lengthy and detailed, dealing largely with the biological aspects of the questions. Wolff-Eisner's work aims to make "the whole science of immunity so simplified in technique and terms as to enable the practitioner to apply modern diagnostics and therapeutics in his work," and this translation is therefore a timely addition to the literature.

The author has attempted simply to point out in a general way the clinical and diagnostic significance of modern immunity research. Phagocytosis, agglutinins, lysins, complement fixation, and vaccine therapy are briefly but clearly discussed. Hypersensitiveness, the so-called anaphylaxis, is dealt with at some length. He presents good evidence to show that this peculiar reaction of the body to heterogeneous albumins may be at the basis of eclampsia, the problems of infant feeding, and the mystery of some idiosyncrasies for foods. A supplemental chapter on salvarsan has been added.

The practitioner will find the volume a source of absorbing interest and great enlightenment, and though he may not himself perform the tests outlined in the text he will be able better to interpret the results and to use them for the solution of the problems that come to him in clinic and practice.

The New Physiology in Surgical and General Practice. By A. Rendle Short, M.D., B.S., B.Sc. (Lond.), F.R.C.S. (Eng.), Hon. Surgical Registrar, Bristol Royal Infirmary; Senior Demonstrator of Physiology, University of Bristol. Price $2.00 net. New York: William Wood & Company, 1911.

This is a useful little volume, containing an account of some of the recent work in physiology, and explaining in simple language its relation to the problems of medicine and surgery. Theories and guesses are omitted, and the author has sifted out from a large mass of details that which seemed likely to be of value in diagnosis and treatment. The subjects discussed are: The thyroid and parathyroid glands; the pituitary gland; studies in digestion and absorption; the applied physiology of blood-pressure; the hemorrhagic diathesis; the physiology of uric acid and other urinary deposits; acidosis, acetonemia, and diabetes; immediate and remote poisoning by chloroform; nerve injuries; the surgical physiology of the spinal cord; cerebral localization; and the action of cutaneous anesthetics. Besides its practical value the book will prove an acceptable supplement to any of the modern works on physiology.

Des Fractures du Rachis Cervical Sans Symptômes Médullaires. By Jules Bœckel, Chirurgien de l'Hôpital civil de Strasbourg; Correspondant de l'Académie de Médecine et de la Société de Chirurgie de Paris; Lauréat de l'Institut; and André Bœckel, Ancien interne des hôpitaux de Nancy; Aide de clinique à la Faculté de Médecine de Nancy; Lauréat de la Société de Chirurgie de Paris. 14 Observations and 20 Original Radiographic Plates. Price 8 fr. Paris: Felix Alcan, 1911.

The monograph is based on 89 observations, including 15 original cases. It opens with a short summary on the gravity of cervical fractures in general and passes to an anatomical description of a specimen of an old fracture of the third cervical, which fracture had given no cord symptoms during life. According to the authors Sonnenburg was the first to call attention to this condition in the living. The most important portion of the work is given to the study of fractures of the bodies of the cervical vertebræ in which there are no cord symptoms. The cause, mechanism, site, symptoms, diagnosis, course, and late complications are fully and ably discussed. Separate chapters are devoted to fractures of the axis and atlas; to fractures of the posterior arc and spinous processes, and to the prognosis, therapeutic indications, and treatment. The seventh chapter takes up the medicolegal aspect; the eighth, cervical fractures caused by firearms. The conclusions are terse and forcible; following these is a chronological list of observations cited in the text, a bibliography, and a series of twenty original radiographic plates. The authors conclusively prove that fractures of the cervical spine can occur without producing the slightest symptom referable to the cord. Such fractures until quite recently have been overlooked or only discovered after the onset of later complications. The importance of the prompt recognition and the urgency of the treatment are insisted upon. In a group of thirty-six cases treated before the radiographic era twenty-two cases died; 61.5 per cent. mortality. In thirty-one cases since this era there were no deaths. The work is a valuable contribution to the traumatic surgery of the spine. A study of its contents will be found most helpful to the surgeon in dealing with a condition which is always fraught with difficulty and danger.

A Handbook of Practical Treatment. By many writers. Edited by John H. Musser, M.D., LL.D., Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and A. O. J. Kelly, A.M., M.D., late assistant Professor of Medicine in the University of Pennsylvania, Philadelphia. Volume III. Price $6.00. Philadelphia and London: W. B. Saunders Company, 1912.

The representative character of this work, which has been so amply demonstrated in the two volumes already published, is again manifested in the concluding volume. This deals with the constitutional diseases, the diseases of the respiratory, digestive, urinary, and nervous systems, and of the muscles and mind. A review of this volume would be inadequate without mentioning the names of its numerous authors. T. C. Janeway contributes the article on diabetes mellitus, and T. B. Futcher that on diabetes insipidus, together with the articles on arthritis deformans, gout, lithemia, uric-acid diathesis, and chronic articular rheumatism. A. W. Hewlett writes on obesity, inanition, scurvy, Barlow's disease, rickets, and osteomalacia. The surgical treatment of arthritis deformans is dealt with by J. E. Goldthwaite. C. W. Richardson contributes the article on the diseases of the nose and throat, and G. Hudson-Makuen that on speech defects. H. Jackson discusses bronchopneumonia, chronic interstitial pneumonia, pneumonokoniosis, abscess of the lung, gangrene of the lung, and tumors of the lung. The articles on the diseases of the bronchial tubes, asthma and hay fever, and pulmonary emphysema are written by J. H. Musser. J. E. Talley is the author of those on hemaptysis, pulmonary edema, embolism, thrombosis, and infarction of the lung, congestion of the lungs, and atelectasis, or pulmonary collapse. The treatment of tracheal and bronchial obstructions is presented by Chevalier Jackson. S. Robinson deals with the surgery of infectious diseases of the lung and pleura. The article on diseases of the pleura is written by J. H. Musser and E. H. Goodman. The diseases of the respiratory system in children are discussed by I. A. Abt. M. H. Cryer writes on the general hygiene of the mouth and disorders of the teeth and gums (including cancrum oris and Ludwig's angina). The article on diseases of the mouth, tongue, and salivary glands is contributed by J. D. Steele and G. M. Piersol. B. W. Sippy discusses the diseases of the esophagus and of the stomach, and the surgery of the esophagus is dealt with by C. H. Mayo. W. J. Mayo contributes the article on the surgery of the stomach and duodenum. The diseases of the intestine are discussed by W. A. Edwards, constipation is discussed by J. H. Musser and G. M. Piersol, and intestinal obstruction and the surgical treatment of constipation by J. G. Clark. Maynard Ladd writes on the gastroenteric diseases of infants and children, C. G. Stockton on diseases of the liver, Roswell Park on the surgery of the liver and gall-bladder, J. M. Anders on the diseases of the pancreas, B. G. A. Moynihan on the special circumstances in operations upon the pancreas, J. Sailer on visceroptosis, J. H. Gibbon on the surgical treatment of visceroptosis, and J. H. Jopson on peritonitis. The article on diseases of the genitourinary system is presented by E. Le Fevre, and that on surgical indications in urinary tract disease by G. L. Hunner. W. G. Spiller writes on diseases of the nervous system, C. H. Frazier on surgical aspects of certain lesions of the central nervous system, E. W. Taylor on diseases of the spinal meninges, spinal cord, and spinal nerves, J. Homans on the surgical treatment of diseases of the spinal cord, F. X. Decum on the treatment of the so-called functional nervous diseases, and H. C. Moffit on vasomotor and trophic diseases, and diseases of the muscles. The article on mental diseases is contributed by J. H. Lloyd. It would be difficult to single out any one of the above articles for special commendation, so admirably do they all serve to make this work one of definitely practical value to the general practitioner, one that he may turn to for guidance in a wide range of activities. The art of the publisher has vied with the skill of the authors in producing a work which will undoubtedly earn a wide popularity.

The Diagnosis of Nervous Diseases. By Purves Stewart, M.A., M.D. (Edin.), F.R.C.P., Physician to Out-Patients at the Westminster Hospital, Joint Lecturer on Medicine in the Medical School, Physician to the West End Hospital for Nervous Diseases and the Royal National Orthopedic Hospital, Consulting Physician to the Central London Throat Hospital. Third Edition, Revised and Enlarged. Price $4.50. New York: E. B. Treat & Co.; London: Edward Arnold, 1911.

There are few books in any language that deal exclusively with the diagnosis of nervous diseases. The fact that French and German translations of the last edition of this work have appeared indicates that it has supplied a distinct want. The author has in the present revised and enlarged edition succeeded in writing an eminently practical volume in which the subject matter is approached from the clinical standpoint. This subject matter is included under the following headings: anatomy and physiology, method of case-taking, coma, fits and other convulsive phenomena, involuntary movements, aphasia, disorders of articulation, cranial nerves, pain and other abnormal subjective sensations, abnormalities of sensation—hyperesthesia, paresthesia, anesthesia, organic motor paralysis of upper neurone type, organic motor paralysis of lower neurone type, recurrent and transient palsies, incoordination postures and gaits, trophoneuroses, reflexes, affections of the sympathetic and angioneuroses, the neuroses, electrodiagnosis and electroprognosis, the cerebrospinal fluid, disorders of sleep, and intracranial tumors. The author shows an exceptional mastery of his subject and of the power of expressing his meaning clearly and succinctly. The numerous illustrations are helpful, and the paper, typography, and binding leave nothing to be desired.

Society Reports.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held February 10, 1912.

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

Address of the President.—Dr. WILCOX, on entering upon a second term as president, made a brief address in which he reviewed the work accomplished by the Association in the past two years.

Sources of Error in the Diagnosis of Diseases of the Spine.—Dr. REGINALD H. SAYRE, in this paper, said that one could not observe cases of spinal disease for any considerable time without discovering that there were many conditions which presented very similar appearances. Personally, he had seen several cases of inflammation of the upper cervical spine showing many of the symptoms of torticollis, and in one of these (the fact not having been recognized that the muscular contraction present was due simply to nerve irritation resulting from an inflamed vertebral joint) preparation had been made to divide the sternocleidomastoid muscle for the relief of the deformity. In several other instances a deformity simulating torticollis had appeared after an inflammation of the middle ear, in two following an operation on the mastoid, in consequence of the second cervical vertebra having become involved; and the same might take place after tonsillitis. The pain present on motion carried beyond a certain point, the muscular spasm restricting motion of the neck, and the slight elevation of temperature should show that such cases were not torticollis, and in all those cases of disease in the first two cervical vertebræ he had observed a symptom which seemed to be typical. These patients would not lie on the back voluntarily except while holding the head in the hands with great caution, as this position caused much pain, which was due to pressure on the inflamed surface. Torticollis might be regarded as a scoliosis affecting the neck, and just as the diagnosis between torticollis and spondylitis was in some cases confusing, so scoliosis and spondylitis might be at times confounded. While in spondylitis, or Pott's disease, the anterior portion of the vertebral bodies was usually affected, not infrequently the spot of inflammation was on one side; so that a lateral, and not an anteroposterior, curve was produced. It was most important not to mistake these lateral deviations for rotary lateral curvature and institute a course of gymnastics in a condition requiring the most absolute restriction of motion. Here, again, the presence of muscular spasm and slight elevation of temperature, as well as the use of the *x*-ray, would serve to clear up the diagnosis.

Having referred to the angular deformity sometimes caused by aneurysms, in consequence of erosion of vertebræ, and the fatal results liable to ensue, from efforts at forcible reduction under the impression that the angularity was due to tuberculous ostitis, the speaker said that relaxation of the pelvic ligaments at times gave rise to pain and disability which might easily be mistaken for those due to a lumbar spondylitis. In these cases, however, it was most uncommon to have any elevation of temperature, and the history should clear up the diagnosis. Many patients suffering from neurasthenia had painful spines, but the sensitiveness of these spines to light touch was quite marked in contrast to the slighter tenderness, as a rule, in the tuberculous spine. In the latter, acute pain was occasioned when motion was given to the inflamed joint, while, in contrast to its rigidity, the neurasthenic spine could be bent in almost any direction. Again, in the neurasthenic spine the temperature was frequently subnormal, while in the tuberculous it was almost always slightly elevated. More difficult of diagnosis were certain cases in women with intrapelvic disorders. Here there were the careful tread, a position suggesting a constant colic, a general uneasy look about the whole figure, and a stoop resembling rather closely that of commencing Pott's disease in the mid-dorsal region; and when all this was accompanied, as was sometimes the case, by a spasm of some fibers of the abdominal muscles giving the appearance of a girdle about the waist, and also spasm of the erector spinæ muscles, the similarity to spondylitis became marked enough to deceive even those of experience. In this connection Dr. Sayre related cases in his own experience. One was that of a patient who five years before she consulted him had been ordered a leather jacket by a prominent physician in Philadelphia, who made the diagnosis of Pott's disease. Later she visited New York, where a college professor made the same diagnosis, which was concurred in by a physician he called in consultation. He first applied a brace of his own, and, finding that this gave no relief, used a Taylor brace. The latter also failing to give comfort, he tried a plaster jacket, which she was able to endure for some three years. After careful examination of the case Dr. Sayre came to the conclusion that her symptoms were more attributable to a uterine disturbance than to ostitis of the vertebræ, and requested a vaginal examination. He found the uterus markedly retroflexed and firmly bound down in the pelvis, and consequently referred her to a gynecologist. The latter performed an Alexander operation, and this resulted in a complete cure.

Forcible Correction of the Spine in Lateral Curvature, with Demonstration of Twenty-five Cases.—Dr HENRY W. FRAUENTHAL, assisted by Drs. H. FINKELSTEIN and ARTHUR S. UNGER, made this demonstration. In addition to the twenty-five patients themselves, numerous photographs and *x*-ray pictures illustrating their cases were shown. Dr. Frauenthal, having referred to the very great frequency of the occurrence of lateral curvature, said the subject was presented with two objects in view: (1) So that in our work along the lines of preventive medicine cases may be detected early and by proper treatment be arrested and cured. (2) To offer this over-correction method of treating badly deformed cases as a means of obtaining the quickest and best results. Incipient curvature was too often overlooked by the general practitioner, or, if recognized, considered of little importance; the parents being assured that the child would outgrow the trouble. The cases presented were patients suffering from lateral curvature which had been corrected by means of plaster jackets (not removable) applied with the patient in a recumbent position, the deformity being over-corrected after the manner of restoring club feet. This fixation in an over-corrected position was based on Wolff's law of function adaptation, according to which if any part of the anatomy is changed from the normal to an abnormal posture, and habitually used, the structures involved undergo a change, extending throughout their entire texture, in order to adapt themselves to the new position. The converse of this law was also true: If a deformity of any part is brought back to the normal and retained in this position, the parts adapt themselves to the new position.

For some weeks, Dr. Frauenthal said, he and his colleagues had been selecting those cases of lateral curvature which were quite pronounced, with rotation of the bodies of the vertebræ and with bony deformity and angulation of the ribs. As preparatory to the treatment, with a view to enhancing the flexibility of the body, there was given a preliminary course of exercies aiming at increasing the flexibility of the spine in flexion (forward bending) and hyperextension (backward bending), and also including bending to either side, rotation of the spine, and stretching the spine by means of the Sayre apparatus. The

frame employed in the over-correction treatment was similar to that of a metal bedstead, with the headpiece about 20 inches higher than the foot piece. A strip of muslin was stretched from the head to the foot of the frame, and the patient having been placed upon this, the spine was over-corrected; after which the body was held in this position by means of gauze bandages. Over the parts exposed to pressure heavy felt, about quarter of an inch thick, was placed, to prevent excoriation of the skin. Then a plaster jacket, made with bandages of various widths, was applied, and the patient was kept in position until the plaster had set and hardened; then the jacket was trimmed out at the top to prevent chafing of the axillæ, and at the bottom to prevent pressure on the thighs in the sitting posture. On the following day the jacket was cut out on the side where the convexity was situated, and the patient was directed to continue the exercises, with daily forced breathing to fill out the hollow side. When first taking up this work, the speaker continued, one was surprised at the marked improvement, and even cures, obtained in a comparatively short time—by jackets applied for only two or three weeks. In no case had skin excoriations or sloughing occurred, and the improvement was so marked after the first jackets were applied that the patients of their own accord begged for their renewal. Although the over-correcting produced a most evident and conspicuous deformity on the opposite side, the improvement so impressed the patients and their friends that the hospital's resources had proved insufficient to meet the demands upon them from this class of cases. The cases of lateral curvature requiring corrective jackets were not the mild ones, resulting from faulty posture, but those due to congenital deformities, empyema, and, more commonly, rickets and infantile paralysis. There was no doubt in his mind that the more rapidly deforming cases were most often attributable to the latter disease, and it was therefore advisable, when cases presented themselves with the extremities affected from this, that a careful examination should be made of the erector spinæ muscles, and repeated every few months. The radiographs and photographs presented, he said in conclusion, would show the improvement in the first twenty-five cases in a series of one hundred now being published.

The Operative Treatment of Pott's Disease.—Dr. Benjamin P. Farrell read this paper. While, he said, the routine had been to apply, in the case of ambulatory patients, either a Taylor brace or a plaster jacket, and a Bradford frame when the recumbent posture was indicated, with the result of a large percentage of cures, yet these forms of treatment had confessedly left much to be desired. Among the well-to-do, tuberculous lesions in the cervical and lumbar regions could be dealt with in a moderately satisfactory manner, but because of the impossibility of immobilization, the repair of similar lesions in the dorsal region, although functionally good, was usually a failure anatomically. Hence, a number of men had been led to attempt operative treatment. After referring to Lange's method of implanting tin-plated wire splints, among the objections to which were the introduction of a foreign body where none was necessary, he said it had long been known from studies on the healed kyphos that a fusion of the posterior aspect of the vertebræ through the laminæ and spinous processes was a method by which nature effected repair. Now, if the surgeon might in a few weeks accomplish the fusion which it took nature months or years to bring about, he could not well fail to stay the course of the disease and limit deformity. Thus considered, the question became simply one of determining the best technique for bridging the intervertebral spaces. Early in 1910 Dr. Farrell assisted Dr. R. A. Hibbs in the studies on the cadaver which led him to a technique which appeared to be satisfactory, both from an anatomical and a surgical point of view. While in these studies, which were carried out, with the co-operation of Professor Huntington, in the anatomical laboratory of the College of Physicians and Surgeons, it was easily demonstrable that in adult and adolescent life, there was always adequate bone in the spinous processes to make the bridge, it was necessary to await a verdict in the case of very young children, which would be based upon actual findings at the operating table. It was gratifying to be able to report now that adequate bone existed at least as early as the third year; therefore the use of autoplastic bone transplants, or any other form of foreign body, was not only unnecessary, but essentially prejudicial. At first the use of such bone transplants had been deemed requisite in the case of younger children, but since then operative experience had shown their uselessness.

Whatever might be the opinion of some regarding the reproduction of bone in this region, it was evidently that of well-qualified histologists that bone reproduction was based fundamentally upon the activity of the periosteum. It was, therefore, necessary to point out concisely the exact treatment accorded this membrane in the Hibbs operation. The main points were: the preservation of the periosteum and of the blood-supply and the prevention of hemorrhage. The first was accomplished by a median section of the membrane through to the bone on both the superior and inferior aspects of the spinous processes; the second, by a scrupulous avoidance of any separation between the muscles and the periosteum. It was a very simple matter to push back the periosteum without any tearing whatever. This produced an almost continuous periosteal layer on either side, constituting, when closed, a periosteal tube which would undoubtedly develop adequate bone tissue whether the denuded fragments were included in the tube or not. It was desirable to strip the periosteum out over the laminæ to the base of the transverse processes, because the laminæ lay very close together, and in consequence of the observance of this detail of technique a fusion took place between them which, with the bridge made by the spinous processes transposed, secured a fusion of the vertebræ from the transverse processes on one side to those of the other. It had been customary to break the spinous processes at their base, placing them in regular sequence, the apex of one leaning against the base of the next. Included in this bridge were one or two healthy vertebræ above and below, as well as the spinous processes of the diseased vertebræ. The fragments were held in place by chromic gut sutures, and the periosteal tube was closed about them. The results of 31 cases operated on to date were satisfactory, and the degree and rate of repair were indicated in a series of radiographs shown. This operation, which seemed to carry with it great advantages over the old form of treatment, had been done without mortality up to the present time. Deformity was lessened, the period of convalescence was shortened, the support was perfectly symmetrical, and the patients were relieved of all apparatus at the end of three or four months.

In addition to the radiographs mentioned, Dr. Farrell presented four patients, one of whom was a young married woman, who had been operated upon and who strikingly illustrated the excellent effect of the treatment.

Dr. Henry W. Berg said he had been particularly interested in the two cases mentioned by Dr. Sayre in which uterine trouble simulated Pott's disease and which were cured by gynecologists. In such cases the question always arose, Was the result due to the operation or were the cases instances of hysteria? In the latter class of cases any kind of operation was likely to have a curative effect. He who was capable of always excluding organic disease must be a very competent diagnostician, and Dr. Sayre had certainly shown a clear knowledge of orthopedic pathology. Many cases of torticollis were met with in general pedi-

atric practice. The torticollis of Pott's disease was very similar in its pathology to that seen in connection with meningitis; both being due to irritation resulting from pressure on the spinal nerves as they passed out through the foramina. There was one diagnostic point which he had found of great importance and one which could nearly always be depended upon. In congenital torticollis the head was drawn by the contraction of the sternocleidomastoid muscle toward the opposite side, while in that due to Pott's disease or meningitis the reverse of this was true. As to Dr. Hibb's operation, the logic of making out of the bone itself a supporting splint was apparent, and the simplicity and effectiveness of the procedure certainly appealed to one. Whether it cured the Pott's disease, however, was another question. In this affection the angular curvature was simply a result, and not the disease itself. The operation in question, it seemed to him, was applicable only to the early cases. In the bad cases he did not see how it was possible to secure the necessary support. He recalled with what horror he had first read of Collet's forcible straightening of the spine in Pott's disease. After the spinal cord had gradually accommodated itself to the V-shaped cavity, such a procedure was liable to cause a rupture of the cord; an accident attended with the most calamitous results. While successful cases were reported, he believed there had been a number of fatal cases which were not reported.

Dr. Dexter D. Ashley said that Dr. Frauenthal and his confrères had certainly presented a fine collection of cases illustrating the different degrees of deformity and the various deformities coming under this head. As to the frequency of lateral curvature, the large hospitals of this country reported it to be the most commonly met with of all deformities except bow-legs, occurring in about 3 per cent. of all cases presented for treatment. In Europe the percentage was 24 to 29, while medical examiners in the schools of St. Louis reported that 80 per cent. of the children had scoliosis, and 75 per cent. was reported from the Philadelphia schools. With this wide range of findings, it was apparent that there had been a lack of understanding and a faulty classification; functional and postural curves, slight physical blemishes, and asymmetrical development being recorded as spinal curvature. As to relative frequency in sex, after the thirteenth year the male suffered from this deformity in the proportion of one to from four to seven females. Many of Dr. Frauenthal's cases had shown improvement. As to the treatment, however, the speaker would consider Dr. Frauenthal's method, rather than Abbott's. Abbott's jackets were roomy in front, permitting the body to fall forward in flexion. The fenestra over the concavity was large, allowing free movement to the rear. Abbott's jacket was a shell in which the body was forced from side to side, and forward and backward, by means of felt pads. We should not only show improvement—any jacket would do that—but must over-correct: and, as Truslow had well said, in an article on this subject, the *x*-ray must be our last court of appeal. In his own cases he had been surprised to find a considerable remaining curve, as revealed by the *x*-ray, when, apparently, the spine was well corrected. Dr. Frauenthal set his patients up in flexion, while Abbott stood his on the head, as it were. Still, the position of flexion was the Abbott position. The device for holding this position might be selected or arranged to suit oneself. Abbott was now working on a device to give greater facility for holding the patient in this flexed position. Dr. Ashley's first conception of the technique of Abbott, as gathered at his first visit to that surgeon, had been erroneous. He noted the felt pads over the convexity, and considered it necessary to force this forward; but he found that, in consequence, his patients suffered unendurable pain. These pads were simply placed as "follow-up" pressure. Abbott had informed him that, when developing his technique, he had several times found and lost again his ability to effect an over-correction. He had had a spine go near to correction, and then drop back again to nearly the former curve, while in the jacket. He himself had also had the same experience. This was due, of course, to overlooking some point in the technique which was essential, but not appreciated. We would have to expect such experiences until our technique became more perfected. This explained why a severe curve was sometimes found to be comparatively easy, and a slight curve particularly trying to both operator and patient. He agreed with Dr. Sayre that the pendulum was now swinging in the right direction. As for himself, he was pleased to be an humble copyist or imitator of the Abbott method at present, and would not therefore attempt to introduce new features until he had convinced himself that he could do better than Abbott. It was to be remembered always that the *x*-ray was our last court of appeal; and no apparent correction in the jacket should suffice. Abbott's advice to the beginner in this work was to select a few cases with slight deformity and work with these until he had succeeded in having them over-corrected. Because of the confusion of detail in a large number of cases and the arduous labor necessary in carrying out the technique and meeting the various conditions as they arose, the handling of a few cases at a time would be much more satisfactory to physician and patient. Dr. Ashley had experienced this himself, feeling that he undertook too many cases at once to bring out his best work.

Dr. S. Kleinberg said that in a careful study of a dozen or more cases treated by the Abbott method his experience had been that the best treatment consisted of infrequent changes of the plaster jacket and progressive packing. He cut out two fenestræ, one at the back, over the hollow, and one in front, over the hollow, and packed with cotton over the dorsal convexity and the prominent ribs in front. On the theory that if a little flexion was good, more was better, he elevated both head and feet. In order to get greater corrective influence, he in some six cases inserted rubber bags over the dorsal convexity, beneath the plaster; but these he had to discard because of severe irritation of the skin. In the cases shown tonight there were no cures, and, indeed, in the short time in which these patients had been treated one could not expect to have even a completely corrected case. During a period of a little over three months he had managed to correct the deformity in one case, but even here this was not yet over-corrected.

Dr. Siegmund Epstein said that, as evidenced by the advances which had been the subject of the evening's proceedings, a new era in the treatment of spinal disease had dawned since 1910. It was true, however, that while the plaster jacket treatment of lateral curvature had been popularized by Abbott, his plan was really an evolution which was the result of previous methods. His method was not original, with the exception that he was the first to put on a plaster jacket with the patient in the position which he advocated. The various cases illustrating the over-correction treatment of lateral curvature which had been shown this evening were certainly most impressive, and when, as was the case in at least one instance, the spine was rendered pliable in four weeks, the result seemed indeed marvelous.

Dr. Sayre said he could not but express his gratification at seeing the results obtained in the four cases of Pott's disease shown which had been operated upon. Personally, however, he had not as yet made up his mind as to the advisability of operating in these cases. The question to be considered was whether a bone splint was better than an external artificial one. In regard to the treatment of rotary lateral curvature there had been in the last few years a great deal of swinging back and forth of the pendulum of

opinion between the advantages of fixation and of free exercises. Now we were getting back to the pressure treatment, such as was found so advantageous in clubfoot. It was a fact, however, that in clubfoot we were able to get a much better leverage than was possible in spinal curvature. Still, he believed that Abbott's idea of over correction and afterward repeating the pressure was a step in the right direction.

Dr. Farrell, in closing, said that the Hibbs operation was not attempted to cure the tuberculosis. It was designed simply to afford an efficient splint. By the breaking off of the spinous processes it also had the advantage of at once reducing the deformity present.

NEW YORK ACADEMY OF MEDICINE

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 23, 1912.

Dr. Franklin A. Dorman in the Chair.

Post-Abortive Septic Fibroid Tumor of the Uterus; Hysterectomy; Recovery.—Dr. Hiram N. Vineberg reported this case. The woman had been married two years and became pregnant for the first time. Dr. Vineberg was called into consultation on November 11, 1911, when she gave the following history. Two weeks previous to consulting him she had had pain in the lower abdomen and her family physician had diagnosed pregnancy complicated by fibroid. On November 1 she miscarried, the fetus being about three and one-half months and the placenta being retained. Immediately following this the patient went into collapse. Under vigorous hypodermic stimulation the patient rallied after about three hours. About fourteen hours after the expulsion of the fetus a well-known gynecologist removed the placenta under narcosis. On November 3 she had chilly sensations and a temperature ranging from 102° to 103° F. By November 11 the pulse reached 130 and the temperature 106.4° F. When Dr. Vineberg saw her she looked deeply septicized and her pulse was 150 and respiration 60. The uterus was found to reach to the umbilicus, the cervix was open and there was a soft mass in the uterus. Although it scarcely seemed probable that the patient would survive the operation, Dr. Vineberg took the chance and performed a hysterectomy. The operation took about forty minutes and offered no technical difficulties. The next day the change was striking; she had a temperature of 101° F., pulse 110, and a perfectly clear mind. Her convalescence was complicated by a breaking down of the wound and phlebitis in the left leg. The interesting points in this case were that so youthful a woman should have such a large fibroid, that there was absence of hemorrhage, although the growth was submucous and the occurrence of pregnancy in the presence of a fibroid growth in that location. This case emphasized in a striking manner that deeply septicized patients would withstand hysterectomy provided it was expeditiously done and without undue loss of blood with even less shock than would occur in a non-septic woman. Dr. Vineberg also referred to two cases, one in a woman 34 years of age and the other in a woman 28 years of age where large fibroids were found after abortion. Both of these tumors were of the submucous variety and neither patient had had any menstrual disturbance to indicate the presence of the growth.

Cesarean Section: Ileus, Enterectomy, Recovery.—Dr. L. J. Ladinski reported this case. The woman was 28 years of age and had had one miscarriage at the fourth month. She was poorly nourished and had a markedly kyphoscoliotic pelvis. She had been having ineffectual labor pains for some time before admission to the hospital on December 24. During the night of December 27 the pains became severe and finally cesarean section was done under ether, a living child extracted, and the patient returned to bed in good condition. On the third day her pulse became rapid and nausea and vomiting started in. The abdomen became markedly distended and the patient had cramps. In spite of medication, lavage and enemata, these symptoms continued and no effectual bowel movement could be obtained. On January 3, it was decided to explore the abdominal cavity. At laparotomy the intestines were found markedly distended, but slightly injected and a small amount of bloody serum was present in the abdominal cavity. A small portion of ileum was found covered with lymph and slightly constricted. The portion above the constriction was withdrawn and incised and a glass tube with a rubber connecting tube tied in, through which gas and feces could be expelled. A rubber tissue drain was inserted in the pelvis and the wound partly closed. Shortly afterwards the bowels moved satisfactorily and gave no further trouble. The glass tube and drains were removed forty-eight hours after the operation and the recovery was from that time uneventful. He could assign no cause for the ileus except the low vitality of the patient and the peculiar contour of the abdomen, or possibly the morphine administred several days previous to the section.

Rupture of the Uterus During Parturition.—Dr. L. J. Ladinski reported this case. The woman was 32 years of age and had had four normal pregnancies, the last child having been born four years ago. The fifth pregnancy was normal, but the presentation was transverse. Podalic version had been performed and the aftercoming head extracted with great difficulty. The third day after her delivery the writer had seen the patient at her home when her pulse was 130, temperature from 103° to 105° F., abdomen greatly distended and tympanitic and the uterus occupied by a large hard tumor extending above the umbilicus, especially on the right side. Vaginal examination revealed the presence of a large fibroid uterus. A large rent was felt in the left border of the uterine wall just above the cervix which communicated with a large cavity caused by the separation of the layers of the broad ligament on that side. The rupture was apparently subperitoneal. The patient refused to go to the hospital and to submit to a hysterectomy. The following day her condition became worse and she consented. The uterus was enlarged to the size of a four-month pregnancy and studded with small fibromata. The lower uterine segment on the left side, including the entire broad ligament extending to beyond the infundibulum was discolored, edematous, swollen, and necrotic in parts. Foul smelling pus exuded from the left broad ligament into the peritoneal cavity. A subperitoneal rupture had occurred separating the cervix from the body of the uterus posteriorly and on the left side, the rupture involving a great portion of the left border of the body of the uterus and separating completely the two layers of the left broad ligament. In the anterior wall of the cervix just above the rupture was a fibroid the size of an egg. The stump of the cervix was removed separately and the two drains were inserted into the vagina from above: one in the left pelvis and one in the right. The patient rallied for a time after an infusion, but died that evening. This case was interesting because of the impediment offered to labor by the small fibroid situated in the anterior wall of the cervix. The rupture was unavoidable and might have occurred in the most skilled hands. The only measure that could possibly have saved the patient's life was a cesarean section, which was out of the question under the circumstances.

Eclampsia Complicating Delivery of a Monstrosity: Hemipagus Symprosopus.—Dr. L. J. Ladinski reported the case of a patient, 27 years of age, who had been married two years, but who had never been pregnant. She was operated upon for bilateral diseased adnexa, ante-

fexion, and stenosis. Two years after this operation the patient returned about three months pregnant; her expected delivery was to have occurred about November 11, 1911. On September 10, the membranes ruptured without premonitory symptoms and a large quantity of amniotic fluid escaped. Examination revealed the os dilated to the size of a dollar and the head presenting. Palpation of the abdomen strongly suggested twin pregnancy. After being in labor about an hour the patient complained of dimness of vision. A specimen of urine examined at this time was negative as to albumin, sugar, and acetone, and contained only a very few cylindroids. Rapid delivery was effected by high forceps. Shortly afterward, about 2 P.M., the patient had several convulsive attacks which under stimulation with strychnine and nitroglycerine ceased, and the pulse, respiration and sight improved. About 8 P.M. she was again seized with convulsions and in spite of nitroglycerine, venesection, etc., she died about 12 P.M. The question arose as to whether the gestation with the monster had anything to do with the production of the eclampsia as the patient showed no affection of the kidney or other organ previously. The specimen was that of a seven months' fetus. The head was ovoid, broader posteriorly and latterly. In addition to one ear on each side of the head there was one just below the occipital protuberance formed by the fusion of two in its anterior surface and having one single auditory canal. As the brain was not removed in its fresh state it could not be studied. At the base of the skull posteriorly at each side a cord was found entering a foramen magnum separated by a ridge of bone into which the external auditory canal beneath the occipital protuberance seemed to enter. The neck was short and thick, and the cervical vertebræ could be felt going to each half of the fetus. The chest was single and on opening it two lungs and one heart were found; the heart was larger than normal. The right lung had four lobes and the left three. Posteriorly the spinal column of each fetus could be seen. From each aorta a branch was given off to the right fetus, anterior to the spinal column and a little beyond it became the descending aorta of the left fetus. The superior and inferior vena cava joined and entered the right auricle; coming from the left side along the posterior wall of the heart was the inferior vena cava of the other side and it joined apparently to the azygos veins. The abdomen was fused together as far as the umbilicus and then became two and continued on each side as a single fetus with its own lower extremities and external genitals showing both females. The umbilicus was fused showing two arteries and two veins. On opening the abdomen an urachus was found going downward in each pelvis to the bladder. Each pelvis had its own tube and ovaries attached. The ductus venosus continued upward and entered about the center of the liver, anterior and to the right. The gall-bladder on the posterior surface extended beyond the free surface. The ductus venosus continued backward and to the left between a loop of intestine to a smaller liver posteriorly, which had its rough surface anteriorly and only a small rudimentary gall-bladder. Posteriorly it had a smooth surface. To the left of the upper abdomen was a spleen about three-quarters of an inch long and which was connected to a pancreas which was between the spleen and posterior liver on each side. On pushing the intestines aside they found another spleen posteriorly and to the right which had the pancreas between it and the right anterior liver. There was only one stomach with a pouch on each side, leading upward into the esophagus and downward into the pylorus and thence into the jejunum; it then divided into two as ileum and continued on each side. There were two kidneys.

Carcinoma of the Clitoris, with Metastases in the Glands of both Inguinal Regions.—Dr. L. J. Ladinski reported this case which occurred in a multipara 58 years of age. The patient's menstrual history was negative, the menopause having occurred twelve years ago. About six months before consulting a physician she had noticed a small tumor about the size of a pea in the region of the prepuce which gradually increased in size and caused her both pain and annoyance. She showed no signs of cachexia and had no other ailment except a bleeding and painful tumor in the introitus vaginæ. Both inguinal regions were the seat of large, hard, and slightly tender glands. A cauliflower-like growth was occupying the site of the clitoris and was connected by a broad pedicle to the upper third of the right labium magnus. A secondary metastatic nodule was seen in the inner surface of the right labium about one and one-half inches below the original tumor. At operation a large carcinomatous mass involving the entire vulva was removed. The inguinal glands were large and adherent. An incision was made on the right side parallel to Poupart's ligament, extending from the anterior inferior spine to the labium major and the glands and fat were dissected free but not removed. A circular incision was then made an inch from the base of the pedicle, the incision embracing the mons veneris above, the labia on either side, and the vestibule to within a quarter of an inch of the upper border of the meatus and the tumor, clitoris, skin, and fat were dissected free. The inguinal glands and tumor were then removed *en masse*. A perforated rubber drainage tube was inserted in the lower angle of the wound and the entire wound closed with Pagenstecher. The left inguinal glands were next removed by making small incisions over these glands. Several small glands were incised. Numerous small lipomata were found, but were left intact. The tumor of the labium was a melanotic carcinoma, corresponding pathologically to the type of new growth previously termed melanotic sarcoma, which was now regarded as epithelial in origin. In all probability the tumor had its origin in a pigmented mole.

Dr. Brooks H. Wells, referring to these pigmented moles, looked upon them as carcinomatous; when they occurred at the mococutaneous junction in particular they were of bad import, and he felt that they should always be removed.

Specimen of Fetus Papyraceus.—Dr. Franklin A. Dorman presented this specimen. The patient from whom it was taken was a primipara. The child weighed about five and a half pounds at term, which was rather unusual in these cases. The patient was watched from month to month, the uterus assumed its proper size, and she was now practically well.

A Preliminary Report on a New Antiserum for Cancer.—Dr. S. P. Beebe and Dr. Berkeley presented this communication, which was read by Dr. Berkeley. (See page 513.)

Clinical Account of Thirteen Cases of Malignant Disease Treated with a New Antiserum.—Dr. Wm. M. Ford read this paper and presented cases. (See page 514.)

A Study of the Integrity of the Uterine Scar After Cesarean Section.—Dr. J. A. Harrar read this paper. Although this operation was now performed very frequently and had lost its septic and hemorrhagic terrors, nevertheless they could not afford to disregard other surgical problems involved. A heavy muscle not supported by facial coverings was cut through, a muscle that might be called upon later to functionate vigorously. In addition to the risk attending the section of any intraperitoneal organ lined with mucous membrane there was the added danger of rupture through or adjacent to the cicatrix in future pregnancies. In 1908 Dr. Broadhead had reported a case of rupture at the site of an old scar and he had collected 10 cases from the literature. Subse-

quently Mauclaire and Burnier summarized 22 cases, 15 of them being repetitions of Dr. Broadhead's cases and seven being new ones. Two cases had been reported in which rupture occurred after two cesarean sections and Cameron had reported a case similar to the one about to be reported. In the majority of these cases there was no detailed description of the ruptured muscles microscopically, and it was not clearly defined whether the scar gave away or the adjacent muscle tissue. In an experimental study by Mason and Williams of Boston on the strength of scars in the uteri of pregnant guinea pigs they proved to their satisfaction that the tissues gave way not at the scars, but through adjacent muscle fibers. The writer had attempted a study of the uterine scars of former cesarean sections in human females by a review of the histories of cases in the Lying-In Hospital and from his personal experience. In his investigation he had selected instances of abdominal cesarean section followed by vaginal delivery, of which there were three cases; descriptions of the gross appearances of the intact scar in 42 cases of repeated cesarean section, instances of marked attenuation of the scar, of which there were four cases; and instances of rupture of the uterus after one or more cesarean sections, of which there were four cases. The writer related the history of three cases in which delivery per vagina after a former cesarean section was practically normal, and said that in 42 cases at a subsequent cesarean section the old scar was described as solid and with no apparent thinning or stretching. In four instances in which the writer had had occasion to perform repeated cesarean sections, the scar in the uterus had been represented merely by a slightly depressed linear whitening of the visceral peritoneum. In 16 of the 42 cases of multiple operation there were adhesions of the omentum either to the uterus or to the anterior abdominal wall. These adhesions did not seem in any way to affect the strength of the uterine cicatrix. It was noteworthy that adhesions when once formed, even if cut off and tied, always recurred and in denser fashion at a later cesarean section. Six times the placenta was found attached over the region of the old incision without impairing its solidity. Seven times the incision in the original operation had opened into the placental attachment. Suture of the placental site in all these resulted in a sound scar as proved at a second operation. In two instances of marked attenuation of the scar the placenta was found directly under the old wound; in one of these the scar was described as soft, irregular, and translucent. In two other cases of attenuation of the scar the placenta was not in relation to the old scar; the thinning had depended entirely upon improper healing of the uterine wound. In these instances convalescence had been febrile and intrauterine douches had been used. One of these thin scars produced by sloughing of the uterine wound was excised at a later cesarean section and was shown to consist at its weakened portion of the peritoneal coat and subperitoneal cellular tissue. The muscle tissue of the wound did not heal primarily. There was a history of stormy convalescence in this case with retention of lochia, for which intrauterine douches were given. The writer related the histories of four cases of actual rupture of the uterus in or adjacent to the old scar that occurred in subsequent pregnancies, one of which had been reported by Dr. Broadhead; the others had occurred in his own experience. In the first case it could not be said from the microscopical appearances whether the rupture occurred directly in the old scar or closely adjacent to it, as the rent went apparently through normal muscle tissue. In the second case the abdominal scar was found to be of the keloid type, the lower end of the old uterine wound looked as though the sutures had given away during the first repair and the uterine peritoneal surface healed over. In the third case the uterine tear was limited to the old uterine wound. In the fourth case the rupture occurred between the lines of two scars made on two former occasions. It was to be supposed that two parallel scars less than a centimeter apart would isolate between them an intermediate danger zone of tissue that had had both its trophic nerve supply and its blood supply intersected and was therefore intrinsically weaker than the muscle tissue distal to these incisions. Examination of sections made at five different points gave no indication of scar tissue in the muscle and it seemed evident that the rupture had occurred through normal uterine tissue. As far as could be observed under the microscope an entire regeneration of the severed muscle fibers had taken place. These four cases illustrated the following teachings, which might be useful in future operations: (1) In undertaking a cesarean section on a woman who had been long in labor, with ruptured membranes and who might be infected, in addition to the immediate danger of septic mortality, they must recognize the probability of obtaining a poorly healed scar that would be a bad risk in a future pregnancy. (2) When performing repeated cesarean sections the old uterine scar should be excised rather than a new incision made parallel to it to avoid the isolation of a weakened strip of uterine wall between the two scars. (3) Intrauterine douches should be avoided in the treatment of retained lochia after cesarean section, not only for the immediate dangers, but especially on account of the risk of mechanical injury to the uterine wound. They must rely upon elevation of the head of the bed and the application of an icebag to the fundus. (4) In the management of a parturient woman who had previously been subjected to a cesarean section for the relative indications, such as moderate pelvic contraction or excessive size of the fetus, or certain types of eclampsia and placenta previa, one must be guided by the history of the previous convalescence as well as by the method of suturing employed; thus only could one be assured of the integrity of the old scar and to what extent it would stand the stress of labor and of vaginal delivery.

College of Physicians of Philadelphia.

At a stated meeting held March 6, Dr. Charles K. Mills presented a communication entitled "The Mechanism of Emotional Expression and Its Organic Basis, Cerebral, Cerebellar and Bulbospinal," illustrated by lantern slides and by moving pictures under the direction of Dr. T. N. Weisenburg. Dr. Mills propounded the view that centers for emotional expression existed in the cerebral cortex in a position in advance of the motor area and were susceptible of stimulation into activity in various ways, the impulses pursuing a somewhat devious course. Interruption of the pathways through which such impulses pass will result in inhibition of emotional expression in whole or in part in accordance with the extent of the disturbing factor. He illustrated the points contended for by him by pictures portraying various emotional expressions induced in the usual way in healthy persons, in other persons, for example, actors, voluntarily, and in patients exhibiting symmetry of action of the face in ordinary motor activity but with a symmetry in emotional expression. Dr. Weisenburg gave a demonstration of moving pictures showing the facial expression in cases of bulbar paralysis, multiple sclerosis, chorea, paralysis agitans, as well as the incoordinate movements of cerebellar tumor, tabes dorsalis and astasia abasia. The discussion was participated in by Dr. George McClellan, Dr. James Hendrie Lloyd, Dr. Smith Ely Jelliffe of New York by invitation, Dr. W. G. Spiller and others.

Drs. Jay F. Schamberg and John A. Kolmer made "A Preliminary Report of Experimental Studies on the Administration of Salvarsan by Mouth in Animals and in Man." It was first shown that the drug could be administered to

lower animals in appropriate dosage without injury, and that arsenic could subsequently be demonstrated in the hair and in the urine. Also the number of bacteria in the wall of the intestine was smaller than in control animals. Finally, the drug was administered by the mouth to human beings suffering from syphilis in various stages, and while vomiting and transitory diarrhea resulted in some instances, improvement in the disease symptoms took place, but this was no greater than could be observed under intelligent treatment with mercury and iodin.

Dr. H. A. Hare made "A Further Report on the Operative Treatment of Aortic Aneurysm by Wiring and Electrolysis," illustrated by lantern slides. He stated that he had performed this operation 26 times in 23 cases and fortunately without accident or complication. Almost invariably the procedure was followed by relief of pain and mitigation of other symptoms. In some cases repetition of the operation was required. By reason of the underlying state of the blood vessels death was the eventual outcome, although in some instances life was prolonged sufficiently for the performance of important duties. In a recent case in which the proper quality of gold wire could not be obtained the material passed down the aorta to a point below the level of the diaphragm, where it could be demonstrated by means of the *x*-ray picture, but without causing any related symptoms. So far as the distinction could be made clinically the operation was applicable to cases of sacculated and not of fusiform aneurysm.

Dr. James E. Talley presented a communication entitled "The Effect of Atropine on the Pulse Rate in Various Conditions of the Myocardium." When the drug was administered to persons without recognizable lesion of the heart the pulse rate was increased between 20 and 30 beats in the minute, probably through a paralyzant action on the terminal filaments of the cardiac branches of the vagus, inhibiting the normal restraining action of this nerve. An analogous effect was brought about in cases in which the action of the heart was previously slowed as a result of the administration of digitalis, both when the heart appeared to be healthy and also when valvular disease and even myocardial disease without disturbance of conductivity existed. In the arteriosclerotic and myocardial cases, on the other hand, in which conducting fibers were affected, the response to atropine was inconsiderable. The observation is thought to possess both diagnostic and prognostic as well as therapeutic value.

Chronic Mediastinitis Superior.—Hutinel states that the mediastinum is accessible to bacterial infection from many organs, being situated between the pleura and pericardium and extending from the upper part of the sternum to the diaphragm. The tonsils, nasopharyngeal vault, trachea, bronchi, heart, and pericardium and the liver and other abdominal organs, may infect the mediastinum and cause connective tissue adhesions. The chief forms of infection are tuberculosis and syphilis. Mediastinitis occurs in children and in adults, presenting the same symptoms in both; in adults it generally results from syphilis and in children from tuberculosis. In children the symptoms are dyspnea, stridor, and dilatation of the tributaries of the superior vena cava. There is dullness over the sternum, but no modification of the respiratory sounds. Radiography shows an obscure shadow around the heart and in the mediastinum. There are frequently enlargement of the bronchial and other thoracic glands. In adults all these symptoms are accompanied by a spasmodic cough, congestion of the face and upper extremities, and attacks of suffocation. There is a diminution of arterial tension in one of the radial arteries when the patient is lying down. By firmly holding and drawing up the thyroid gland one may perceive the rhythmical pulsations of the transverse aorta transmitted to the neck.—*Le Bulletin Médical.*

Medicolegal Notes.

Admissibility of Evidence as to Result of Assault.—In a prosecution for assault with a deadly weapon with intent to kill after the accused had shot the complainant, a shot striking her on the hip, shattering the bone, he dragged her into an adjoining room, where he threw her to the floor, and then with his knees upon her chest choked her until she lost consciousness. A physician who attended her immediately after the assault was held properly permitted to testify that at the time of the assault the complainant was three months with child and as the result of the assault suffered a miscarriage. The second assault and its attendant circumstances were essentially a part of the *res gestæ* of the first assault and therefore the result and consequences of the second assault were equally as admissible as a part of the *res gestæ* as the result and consequences of the first assault.—People *v.* Kafoury (Cal.), 117 Pac. 936.

Insurance—What Constitutes a "Medical Examination."—In an action on a policy of life insurance the case turned largely on whether or not the deceased had submitted to a medical examination within the meaning of the first premium receipt, which provided that the insurance would be in force from the date of the medical examination. The insured was examined on the day the receipt was granted, but died before either the application or the medical report had been forwarded to the company. The company declined to pay the insurance, upon the ground, among other things, that no medical examination had been made. It was held that the medical examination contemplated by the receipt was evidently a final examination, or an examination that the applicant desired to submit to the company as a part of his application. When a report of a medical examination is retained by the medical examiner under an arrangement or agreement with the applicant that it shall not be forwarded to the company until another examination is made it is not an examination within the meaning of the receipt. The medical examination intended by the language of the receipt means a medical examination made by an agent of the company to be forwarded to it, not a medical examination to be retained by the examiner at the request of or under an agreement with the applicant. It appeared from the evidence that the medical examination of the applicant disclosed that he was not an acceptable risk, and that at the end of the examination, when that condition was known the medical examiner suggested that the applicant submit to another examination, and if it appeared that the symptoms he then found, and which induced him to believe and report that the applicant was not a proper subject for insurance, had disappeared, he would make another and more favorable report and forward it to the company. The applicant agreed to that arrangement and the physician took the report of the examination to his office and retained it until after the death of the applicant. The insurance company's agent, who was present when the examination took place, also retained the application, intending to forward it to the company with the medical report thereafter to be made. There was, however, some conversation between the medical examiner and the applicant's wife over the telephone as to which she testified that the examiner requested the applicant to come to the office for another examination and she asked him to turn in the report already made to the company. If that evidence were accepted, the company would be liable for the medical examiner's failure to promptly forward his report. After he was directed to do so he held it as the agent of the company. If the company was under a duty to promptly act on the application and notify the applicant of his rejection, it could not shield itself from responsibility by the fact that the application and medical report had not been received by it, and therefore it could not act.—Northwestern Mutual Life Insurance Company *v.* Neafus, Kentucky Court of Appeals, 140 N. W. 1026.

Admissibility of Expert Evidence.—In an action against a railroad company for personal injuries it was held to be inadmissible to ask a medical witness for the plaintiff if it was not a fact that people having damage suits against railroads and other causes for simulating injury could and did fool physicians to a great extent about what was the matter with them when it was an internal injury. It was permissible to show that the plaintiff's alleged injuries were of such a nature that a physician could not determine with certainty their existence or non-existence; but that other persons had been able to deceive other physicians as to other alleged injuries was irrelevant and immaterial as to any legitimate inquiry in the case.—Ft. Worth & Rio Grande Railway Company *v.* Neal, Texas Court of Civil Appeals, 140 S. W. 398.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

HONAN'S HANDBOOK TO MEDICAL EUROPE. By JAMES HENRY HONAN, M.D. 201 pages, with maps of Berlin, Edinburgh, London and Paris; cloth; price $1.50 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

ELEMENTS OF HYDROTHERAPY FOR NURSES. By GEORGE KNAPP ABBOTT, M.D. 273 pages; illustrated; cloth. Review & Herald Publishing Association, Publishers, Washington.

FOURTH REPORT OF THE WELLCOME TROPICAL RESEARCH LABORATORIES AT THE GORDON MEMORIAL COLLEGE, KHARTOUM. Vol. B.—GENERAL SCIENCE. By ANDREW BALFOUR, M.D., B.Sc., F.R.C.P., D.P.H., Director. 333 pages; illustrated; cloth; price $4.50. Toga Publishing Company, Publishers, New York and Montreal.

THE FRIENDS OF THE INSANE, THE SOUL OF MEDICAL EDUCATION AND OTHER ESSAYS. By BAYARD HOLMES, M.D. 270 pages; cloth; price $1.00. The Lancet-Clinic Publishing Company, Cincinnati, Publishers.

PROCEEDINGS OF THE FIFTH ANNUAL MEETING OF THE ASSOCIATION OF LIFE INSURANCE PRESIDENTS. Held in the Hotel Astor, New York, N. Y., December 13 and 14, 1911. 131 pages; paper.

HEALTH AND MEDICAL INSPECTION OF SCHOOL CHILDREN. By WALTER C. CORNELL, M.D. 614 pages; illustrated with 200 half-tone and line engravings, many of them original; cloth; price $3.00. F. A. Davis Company, Publishers, Philadelphia.

CONTRIBUTIONS À L'ETUDE DU TRAITEMENT DES TUBERCULOSES EXTERNES PAR LES INJECTIONS MODIFICATRICES. By Dr. JACQUES TRIBES. 82 pages; illustrated; paper; price $2.00. A. Maloine, Publisher, Paris.

PHARMACEUTICAL BACTERIOLOGY. By ALBERT SCHNEIDER, M.D., Ph.D. 237 pages; with 80 illustrations; cloth; price $2.00 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

UROLOGY. By RAMON GUITERAS, M.D. Volume I. 667 pages, with 643 illustrations in text and 7 plates; cloth. D. Appleton & Company, Publishers, New York and London.

UROLOGY. By RAMON GUITERAS, M.D. Volume II. 757 pages; with 643 illustrations in text and 7 plates; cloth. D. Appleton & Company, Publishers, New York and London.

DISEASES OF THE NOSE AND THROAT. By ST. CLAIR THOMSON, M.D., F.R.C.P., F.R.C.S. 791 pages; with 18 plates and 204 figures in the text; cloth. D. Appleton & Company, Publishers, New York.

DISEASES OF THE GENITO-URINARY ORGANS. By EDWARD L. KEYES, JR., M.D., Ph.D. 975 pages, with 195 illustrations in the text and 7 plates, four of which are colored; cloth. D. Appleton & Company, Publishers, New York and London.

THE SURGERY OF ORAL DISEASES AND MALFORMATIONS. By GEORGE VAN INGEN BROWN, D.D.S., M.D., C.M. 740 pages; with 350 engravings and 21 plates; cloth. Lea & Febiger, Publishers, Philadelphia and New York.

TUMORS OF THE JAWS. By Charles L. Scudder, M.D. 301 pages, with 353 illustrations, 6 in colors. Cloth, price $6.00 net; half morocco, $7.50 net. W. B. Saunders Company, Publishers, Philadelphia and London.

WHO'S WHO IN SCIENCE. 1912. By H. H. STEPHENSON. 323 pages; cloth. The MacMillan Company, Publishers, New York.

DIE CHRONISCHE ENTZUNDUNG DES BLINDDARMANHANGES. By Dr. FRITZ COLLEY. 244 pages; paper; price 6 M. August Hirschwald, Publisher, Berlin.

THE TOBACCO HABIT. ITS HISTORY AND PATHOLOGY. By HERBERT H. THISWELL. 246 pages; price $1.40; cloth. P. Blakiston's Son & Company, Publishers, Philadelphia.

Medical Items.

Virulence of the Feces of Pneumonia.—Gioacchino Breccia states that the virulence of the feces of the pneumonic patient depends on the presence in them of the *Diplococcus capsulatus* of Frenkel. In a case examined by the author he found that the intestinal lesions were such as to cause only slight anatomical changes, limited to diffuse hyperemia of the intestinal mucosa without any croupous alterations. The author has shown that this germ may traverse the organs of the body without causing any exudative reaction or any characteristic inflammation. He examined the feces of pneumonia patients who presented no intestinal symptoms at various periods of the disease, and injected portions of the feces into animals. He showed that there was definite toxicity of these feces for white mice. He injected feces also into rabbits. He concludes that the feces of pneumonia have a definite toxicity for animals, causing death in a period varying from 12 to 36 hours after subcutaneous injection. The blood of such animals showed the diplococci of pneumonia. The same result was obtained from subcutaneous and intravenous inoculation.—*La Riforma Medica.*

Proteolytic Ferments in the Feces of Nursing Infants.—A. Filia has tested the feces of normal and atrophic babies fed on breast milk and on the bottle. The results vary but little in these various types of children, the quantity of ferments found in the feces being about the same. The causes of variation in the amounts of tryptic ferments are many and various; not depending entirely on the integrity of the pancreas. Variation depends on the quantity of food absorbed by the intestines, on the greater or less activating power of enterokinase on pancreatic trypsin, etc. The meconium was examined immediately after and twenty-four hours after birth, with the result that the ferments were found present and active in it. The author considers that at birth the pancreas is tryptically active, and activity of the enterokinase is shown. This activity is not modified by feeding nor by the condition of development or atrophy and the ferments are present even in meconium.—*Il Policlinico.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended March 8, 1912.

Places	Date	Cases.	Deaths
CHOLERA			
China: Hongkong	Jan. 14-20.	1	1
Dutch East Indies	Nov. 26-Dec. 2	1761	638
India: Calcutta	Jan. 14-20		50
Madras	Jan. 21-27	15	13
Madras Presidency, Dec. 1-31	Cases, 6,557; deaths, 4,130.		
Indo-China: Saigon	Oct. 13-Jan. 24.	63	49
Tripoli: Tripoli	Oct. 13-Jan. 24		
Cases, 2,000; deaths, from 1,000 to 1,200[2]			
Turkey in Asia			
Provinces in Asia and Europe, Apr. 16-Dec. 30, 1911 excluding Constantinople		Deaths, 6,111.	
Manila: among troops			
Acre	Jan. 21	7	6
In vicinity			
Turkey in Europe: Constantinople	Feb. 2-3	2	
YELLOW FEVER			
Brazil: Manaos	Jan. 21-Feb. 3.		5
Pernambuco	Jan. 1-15		2
PLAGUE.

THE PATHOGENY OF MENTAL DISEASE;

WITH SPECIAL REFERENCE TO THE MINOR PSYCHOSES.*

BY ALLAN McLANE HAMILTON, M.D.,

NEW YORK.

THERE is no term in medicine that is more often improperly used than "insanity," and none so indefinite, so susceptible of many interpretations, and in a way so valueless. Much of this is due to the fact that in reality insanity is not a disease but an expression of a derangement, or, as White[1] puts it, "Insanity cannot be spoken of as a disease any more than hyperchlorhydria; it is but a symptom—a type of reaction, an effort upon the part of the individual to meet conditions."

Being a relic of other times, the term is generally used to characterize all kinds of mental disturbance, that may vary from a simple physiological change to a conspicuous, easily diagnosed, and advanced organic deméntia. Its very etymological construction is an apology for ignorance, yet it is an improvement on "madness" and "lunacy," as well as others which were in vogue less than half a century ago. For the want of a better and more exact substitute it retains its place and is often the despair of psychiatrists.

However, after all, *insanity* has been applied so far as possible by experienced alienists to conditions evinced by a *protracted* departure from the usual mental health, or involving more or less disease of the brain. With this significance it after all possesses greater value than any other available definition. Much quibbling, nevertheless, is indulged in as to its use, and it is no wonder that some physicians, judges and juries, and others having insufficient knowledge, time, or inclination, are often befogged. The public, especially, entertains many erroneous ideas regarding mental disease in general, and Stedman[2] has laid much stress upon these misconceptions, familiar to, and explainable by, most of us, either in private practice or asylum work.

These include many popular fallacies regarding the apparent increase of insanity, which after all is not always real, the prevalence being really due to inexact statistics, to the failure to discriminate between first and recideval admissions to institutions, as well as the neglect in taking into account the increase of population of the particular district, or the world at large.

This want of knowledge also leads to error regarding the etiology of mental disease, undue weight being attached to fright, shock, and other exciting causes, as well as to the importance of the climacteric in women; even the influence of heredity is unduly magnified. Ill-informed people likewise entertain many wrong and extreme ideas regarding consanguinity.

Finally there is great diversity of opinion as to what really constitutes insanity, and how the mentally afflicted should be cared for and treated.

The making of a clear and definite demarcation between states of mental disorder in the apparently normal individual and those of graver content, is sometimes a troublesome matter, and our advanced knowledge of psychiatry must lead to the conviction that after all it is the study of the psychological, biological, and biochemical factors that should engage our attention, and if a satisfactory conclusion is desired, each case is to be studied on its merits, and each individual is to be considered with regard to his past history and home life, the latter especially for the purpose of recognizing fresh departures from the norm.

The general physician, as well as the psychiatrist, is sometimes misled by slighting these things, and in seeking to classify the symptoms presented by the aid of hard and fast rules, and the schematic tables laid down in dogmatic, and possibly obsolete, textbooks, few of which stand the test of everyday experience.

The attempt to condense the terminology of the psychoses into narrow limits is therefore by no means always practicable, and there is no more striking example of this arbitrary method than the classification of Kraepelin and his followers, who virtually group most disorders not due to coarse cerebral disease or toxemic influences into two great classes, which chiefly include manic-depressive insanity and dementia precox.

While not denying the convenience of this system, I think it cannot be accepted unreservedly by those of us who have spent a great many years engaged in this field of work; other writers, on the other hand, err in diffuseness of arrangement and division, and this, too, may lead to error and confusion. The modern tendency to study mental disease with reference to normal psychology has within a few years received fresh stimulus from Störring[3] and the etiological investigations of Hoch, Meyer, and others. It has always been my belief that these disorders were, after all, really the *disruption* or *involution of normal habits*, of feeling, thinking, and acting, as the result of other disease, or appearing coincidentally at the point of breaking strain in defective individuals, or with futile attempts at readjustment.*

Within the past few years, according to the advanced deductions of Freud, Jung, and their school, not only hysteria, but some other psychoses are said to owe their origin to the receipt of an early sexual shock or trauma which at the time made a per-

*Elaboration of two lectures delivered at Cornell University Medical College, 1901-1902.

*This view was expressed by me at a meeting of the N. Y. Psychiatrical Society, Nov. 4, 1903.

manent impression, but which subsequently is not recognized exactly by the individual in all its proportions, but asserts itself throughout life in many disquieting ways.

Freud's theory of the effect of this forgotten or larvated psychic insult is that "like a buried memory it lurks along with the corresponding affect in the subconscious, and like a foreign body in the soul causes permanent or recurrent states of excitement in the neuropsychic apparatus."

Both Breuer and Freud believe that the mischief arises from the fact that upon receipt of the psychic trauma there is no adequate reaction, especially of a psychomotor nature, and that finding no vent there is repressed and concealed energy which is the basis of subsequent widespread disorder. In such a case the early exciting cause (*i.e.* psychic trauma) was not followed by "motor discharge, speech, gesture, play of features, tears, laughter, movement of anger or hate, etc."[4]

While we cannot unreservedly accept Freud's theory of early sexual shock and a submerged morbid impression, there is little doubt that unrecalled and maladjusted insults to the mind of many kinds, during its evolution, may result in very decided thought and emotional disarrangement, some resulting psychoses being of an obstinate and almost intractable nature.

More recently there has been a tendency to ascribe the early trauma not only to a sexual shock, as Freud originally held, but very properly to repressed emotional injury of other kinds incident to accident, fright, and sudden grief.

In obsessional disorders especially we find Freud's doctrines of avail, although his line of reasoning leaves something to be desired, for he often unsuccessfully couples with an early sexual incident an easily explainable obsession with no such history.

Macfie Campbell[5] has done much to apply psychoanalysis to the formal differentiation in diagnosis, which is the method that concerns itself with the more objective analysis of the disorders of mood, of the stream of thought, and of the volitional discharge as well as the disturbance of the healthy harmony between mood ideation and general reaction, but he does not think that this should be considered alone without the analysis of the meaning of the patients' reaction to the contents of his inner life.

The latter may be called the *method of subjective analysis,* and it is inconceivable how the two forms of investigation can be divorced, and so far as recent histories of a large number of cases are concerned it would appear as if most of them presented Freud's requirement—that is to say, a larvated trauma.

Until recently the disposition of psychiatrists has been to disregard largely the temperamental or environmental influences which under stress also favor the development of certain insanities. Hoch has, time and again, called attention to the habitual moods and variations of feeling of those individuals who present the picture of dementia precox, and by this method there should be no difficulty in determining the kind of soil in which paranoia and other psychoses grow. Störring gives due weight not only to physiological variation but to the mechanism and shadowy genesis of mental disorders which without question have been at once regarded as pathological. While his conclusions are not always those that have been accepted unreservedly by psychiatrists, they show that many variations heretofore regarded as indicative of extreme mental disorganization are simply reasonable variations from the norm, and are not to be explained in the conventional way. This is particularly true with regard to some delusional psychoses where fixed ideas are simply the outgrowth of normal emotional beginnings, and he disagrees with Hitzig, Kraepelin, and others on many points of accepted psychopathology.

In the interpretation of certain types of symptoms which betray altered personality or deterioration, it does not do to draw hasty conclusions. In fact much of the hair-splitting of modern and fanciful diagnoses would indicate that the psychiatrist has accepted a normal basis of too high a character. While of course the real test is the persistent and gradual mental degeneration so that evidence of weakening and change are apparent, it does not do to forget that ignorant or emotionally religious people may under slight excitement say and do things that are but exaggerations of their normal life. This disposition to accept as evidence of deterioration the emotional or other manifestation of an undisciplined mind is a feature of some of the recently and minutely reported cases of alleged dementia precox.

So, too, if we are to accept the theories of extremists, it will be difficult to refrain from the conclusion that almost every individual is psychopathic. The varying changes that have been called cyclothymic are apt to be exaggerated, for many of them may be simply moods or alternation of feeling in ordinarily sane people.

It is nevertheless true that there may be at times an exaggeration of natural habits and traits through the influence of disease or even physiological variations. Coombes Knapp[6] says, very properly, that "mental depression, explanatory delusions, certain actions of the insane are but normal manifestations brought about by diseased mental states. Other conditions, slowness of thought, resistance to commands, attempts at would-be wit, even Ganser's syndrome itself, may be merely the mental characteristics of a stupid, pert young person who ordinarily has no restraint or good manners. Much of the affectation, posing, mannerisms, and romantic dreaminess of the precocious dement, if an adolescent, is but an exaggeration of the normal characteristics of adolescence so well described by Marro."

He points out that "we lack, furthermore, sufficient information as to the modifications in these various psychical phenomena brought about by disease in different forms, or by *physiological changes in the economy.* We have certain studies, it is true, of the psychical symptoms of a few diseases which affect the mind predominantly, but we still lack psychical studies in cases of ordinary disease, or psychical studies made under varying *physiological conditions.*"*

A broad survey of the field then must convince us, as has been said, that insanity is, after all, a derangement and not an entity; it expresses a rather extensive disorder or dissociation of the operating faculties through disease—a disharmony, so to speak—due generally, it may be said, to a disruption of the mental habits.

It would be a work of supererogation to detail these or the well-recognized psychic operations of the normal individual; suffice it to say that each per-

*The italics are my own.

sonality represents a growth and final development and is the result of education, environment, and efforts at adjustment in those who more or less differ. No two sane persons therefore are entirely alike, nor do they cerebrate in the same manner. Even though brought up under the same circumstances and surroundings, there is a distinct variation in evolution and ultimate individual personality.

The perceptional activity, richness of concept-formation, capacity for subsequent symbol-grouping, facility of association, energy of conclusive judgment, emotional sensibility, and exercise of will are balanced differently, and the mental equilibrium of a number of subjects differs materially, but there is a *mean* which ordinarily constitutes average normal integrity, and an adjustable personality—that is to say, a personality which enables the individual to live in harmony with his fellows and to betray no evidences of conduct that are out of the ordinary; moreover, his own *métier* is not changed except in a natural manner incident and due to senescence. When through the influence of a variety of causes his stability of mental habit is interfered with, a tendency to involution exists, and a variety of eccentric disturbances follow this upsetting. Sometimes these determining interruptions are psychic, again they are due to physical causes. Only too often are they the result of defective heredity which handicaps the subject, and although he goes on adapting himself to the ways of the rest of his kind, and his surroundings, an undue strain may prevent him from exercising the developed habits as he has up to this time—insynchronism and thought incoordination results, while an immediate departure from the habitual standard of feeling, thinking, and acting occurs and we say he is insane.* The conventional operations of thought manifested in conduct, as a rule, permit him to go through life without any other reputation than that of sanity. If these are interfered with we recognize among other things an undue preponderance perhaps of emotional susceptibility, of feeble judgment and delusional tendencies; of defects of perception, ideation, and memory, and the various irregularities in the exercise of volition.

The true way to study mental derangement, then, is so far as possible to depend upon the aid furnished by the study of normal psychology, psychiatry being its antithesis. In this connection too much importance cannot be attached to the investigation wherever possible of the antecedents of the individual, especially those which no one thought worthy of recognition before the first open evidences of the psychosis were shown. The study of ordinary human nature therefore is indispensable to the psychiatrist. Bearing these things in view, it may be seen how easy it is for an evanescent or even a more or less prolonged exhibition of mental derangement sometimes to disappear entirely, or occur at intervals in persons who are apt to succumb to a lowering of tone, due to a variety of physical causes, or an interruption in the personal accommodation of their ordinary mental integrity as the result of habit formation. So important is this whole matter that modern psychiatrists are studying the actual departure, in well-developed psychoses, from the standpoint of ordinary mental health for a prolonged time previous to the actual appearance of the insanity. In this way the special color of a collection of symptoms may be detected when attention is directed to the ordinary peculiarities of the deranged person. All the minor history of habitual moods, suspicions, irritability, reactions following stimuli and central impulses, and the increased susceptibility of the patient to act upon local impressions and insufficient suggestions, furnish indices which are exceedingly valuable and important. Heretofore, and by some today, the tendency has been to analyze syndromes, if it can be called analysis at all. We should not always take morbid expressions as things of new birth, or draw hard and fast lines, or lose sight of disorders which are after all natural forms of departure consisting in the accentuation of mental habits already formed and of long standing.

For the purpose of assistance certain mental and physical abnormalities may be tabulated, and these will direct the attention of the clinician to familiar mental defects that indicate constitutional dominance, they being reflected in the psychosis that eventually develops. Some of the so-called *mental-stigmata* may be enumerated as:

Extreme shyness, secretiveness, morbid timidity, introspection and self-catechism, over-conscientiousness, hyperanalytic tendencies, suspiciousness, seclusiveness, constant pessimism, indecision, vacillation and other indications of the "*shut in*" personality, eroticism, homosexuality, masochitistic and sadistic inclinations, morbid susceptibility, fetichism, jealousy, hypersusceptibility to inadequate impressions, or to affront; cruelty to animals; moral weakness, such as lying and romancing (pseudologia fantastica), purposeless or obsessional theft, "pyromania"; abulia, dullnes of comprehension, distractability, so-called "genius," one-sided aptitude at the expense of other things, especially musical or mathematical talent, slowness in acquiring ordinary knowledge, weak retention of things perceptive, etc., etc.

Among the *physical stigmata* which may or may not be present in persons predisposed to mental disorder, are exaggerated psychomotor activity, speech defects, tics of various kinds, convulsions; cranial asymmetry, defects of palate and teeth, unilateral atrophy of face or tongue, evidences of infantile or prenatal disease or defects, weakness of ocular muscles, pigmentation of irides, peculiarities in development and shape of ears, including Darwinian tubercle and defective lobule, malformation of genital organs, inversion of toes, peculiarities of gait, and possibly the residual objective symptoms of organic disease of the cerebrospinal system.

This collection is simply presented as a reminder that in predisposed psychopathic persons some or many of them may be found in varying degrees. It has been the custom to speak of these subjects and to dismiss them with the statement that "the psychopath does not see things in their proper light" (De Fursac). There is no standard of psychopathy, but there is the general want of mental balance which is indicated in the foregoing paragraph.

The constitutional psychopath is always a degenerate, and his defective make-up invariably favors the growth not only of certain classic insanities, but of mental peculiarities as well, which in their way are quite as important. As his defects come with him into the world and subsequently

*White calls attention to the three things needed by the individual who adjusts himself to his environment. The first implies a knowledge of the same, the sensorium being normal; the second, the association and relation of such knowledge with previous experiences, the intellect assisting him; third, the transformation of knowledge into volitional reactions.—*Psychiatry*, p. 2.

hamper his adjustment, we find that even in childhood he is regarded as "queer," dull, or different from other children, and at a later period is unable to adapt himself to the ways of his fellows and therefore gets into trouble.

He is apt to be one-sided, impulsive, and unstable, full of visionary impulses, and plans in a fussy way for his own benefit and for that of society at large, but his efforts and projects usually come to naught, and his lofty endeavors cause him to be looked upon as a "crank" or worse. Full of hyperquantivalent ideas, he magnifies trifles, or forms an exaggerated estimate of his own importance. It is he who floods the courts with ridiculous law suits, which he invariably loses; or, again, he bores the public with ill-judged projects for reform that are not needed. He identifies himself with absurd movements for the supposed betterment of man or animal, becoming a perpetual nuisance. His euphoria leads him in his enthusiasm to lie or libel, and his mental infirmities do not improve with time. Such people are often restless, and this unrest finds relief in letter writing or persistent telephoning for no apparent purpose. They may be superficially brilliant in a limited direction, but in the main are dull and commonplace. One example writes learnedly upon "thought transference" and illogical occultism, but he has delusions about those who oppose him, and attacks the unsympathetic listeners whenever the opportunity offers, threatening them by disorderly letters or telegrams. Another stirs up the newspapers and the public by dangerous and disquieting attacks upon capital, while he accepts the last suggestion of every unstable and equally crazy reformer who finds his ear. Another is a wanderer and vagabond, eking out a precarious existence from a world which is "down upon him" or "owes him a living."

These people are often dull so far as the capacity for association and the acuteness of anterograde memory is concerned. They have little creative imagination and when at school rarely see the application or purpose of what they try to learn. They are conceited, intolerant, and often pessimistic, and inclined to take violent and utterly unwarranted prejudices.

Their conduct is such that the authorities or anxious friends invoke the interference of the law. At such a time their psychopathic condition may have advanced to an incapacitating degree, but they often appear much better than they really are when aroused by a knowledge that they may lose their liberty. They are thus often able to face the ordinary jury, and for a time present a comparatively rational appearance.

II.—THE MINOR PSYCHOSES.

It has been the custom to classify neurasthenia, hysteria, sexual psychasthenia, epilepsy, and the obsessional disorders as apart from insanity proper. This, after all, is an arbitrary exclusion, for the importance of these conditions is relative: they often bear a close relation to each other, and are sometimes coexistent, forming a syndrome of greater or less importance.

Neurasthenia.—This disease of "fatigability and irritability" (Meyer) is not regarded as it once was, and cannot be clearly isolated, for it is especially associated with obsessional states, hysteria, and sexual perversion, and these may be features of many definite and important insanities. Freud recognizes a form of neurasthenia which he calls the anxiety-neurosis (Angst-Neurose) which usually has a sexual explanation, being due to masturbation, and it is usually a mild psychosis. As a rule, however, there is difficulty in making a clear demarcation between any of the familiar forms of the neurasthenic disorders which we commonly meet, and many others developed by physical or mental shock such as that received in railway or other accidents. There is apt to be a close association between neurasthenia and hysteria in a hybrid psychoneurosis, as it were. The familiar neurotic expressions—subjective or objective—of both diseases are commonly associated and the mental syndrome is sometimes very complicated, but always distinctive. An anxiety-neurosis, therefore, does not of necessity spring from a sexual root.

No greater mistake can be made than to say that the minor psychoses are apt to be evanescent disorders or of little moment, as has sometimes been done, for ordinarily an underlying psychopathic organization exists. It is the experience, I think, of most physicians that in all of them recurrences or aggravations are not unusual, and that they are not always effectually suppressed or cured by the resurrection or demonstration to the patient of the original latent sexual idea, or by subsequent psychotherapy, but they may disappear with the establishment and exercise of conscious inhibition.

While mild psychasthenic symptoms are sometimes likely to be found in apparently normal persons as the result of shock, it is not the opinion of the writer that any prolonged manifestation of any of the psychoneuroses occurs unless there is some constitutional susceptibility. In opposition to this idea Steierlin[7] has observed psychogenetic affections, consisting chiefly of exhaustion, in individuals who, he says, are free from neuropathy. These consist of acute fright-psychoses and hystero-epileptic disturbances of short duration consecutive to railroad accidents, earthquakes, and other great calamities. He even claims to have seen chronic psychoneuroses due to such causation in non-predisposed individuals.

It would appear, however, from Steierlin's investigations and conclusions that it is almost impossible to exclude the subjects in which there is really a predisposition.

My own experience with railroad cases, which is very extensive, convinces me that a case without some psychopathic history is the rare exception.

Hysteria.—No definition of hysteria can be regarded as altogether satisfactory, and to-day its pathogeny remains largely obscure; to speak of it merely as a dissociation of personality is often to beg the question, and is but a theoretical means of elucidation. Though it usually consists of a combination of certain somatic and mental symptoms the former may be ill-defined or entirely absent, but the latter under some guise are always prominent.

It is, indeed, a subtle arrangement, consisting of two striking essentials—a perversion of the will and an emotional instability, and "a dissociation between the emotional tone and the ideational content." (Linenthal and Taylor.) There is always some impairment of memory, and at times more or less confusion. Unexpected reactional response, perhaps to the latent memory of a dream, accounts for the unexpected in the subject's conduct. Inhibition is not so thoroughly or in the same way interfered with as it is in such a psychosis for instance, as acute mania or other disorders connected

with elation; but it would appear as if the normal mental operations were thrust for the time into the background, and as if a riotous series of reactions due to subconscious activity denoted the absence of coordination or inhibition. Then, again, the sudden return of control is usual in hysteria, but not in mania. De Fursac has referred to hysteria as dependent upon "a predominance of the automatism over the voluntary and conscious psychic operations."[8]

The tendency to automatism is seen in the reproduction of subconscious states quite independent of the higher mental life of the individual and outside of his cognizance—and such reproduction is facilitated by excessive emotional stimulation. It is often a quasi-conscious happening, and is akin to a dream state. Ideational activity and association are interfered with—being acts in the dark, as it were; the resultant emotion, the knowledge of the causes of which is denied the patient, often creates only fear, anxiety, or demoralization. The expression of such disorder may be an alteration of conduct which expresses the original disagreeable exciting concept. The initial experience may have been fully accepted and realized, but the subsequent operation of the higher mental apparatus is suspended and the subject is not aware of its importance or full meaning.

In predisposed hysterical subjects it is not uncommon to find certain physical evidences which must needs be mentioned, and when present possess diagnostic value, although their characteristics are inconstancy and irregularity. There may be associated sensory stigmata consisting usually of an irregularly distributed anesthesia in which analgesia predominates; these fields of diminished sensation have abrupt limitations and may bear no regular correspondence with nerve distribution. At times they affect one-half of the body; again they may involve one or both hands or the tips of the fingers to the wrist, and to this the name of gauntlet anesthesia has been applied, or it may be found in spots.

Again, the field of vision is constricted. Not only anesthesia but hyperesthesia is found in this way, or both forms of disturbed sensation may be associated in symmetrical regions in the same individual.

Again, there are a vague dysesthesiæ, globus, and motor disorders of varying kinds, profound abulic paralysis, contractures, tremor, and even convulsions.

In erotic cases such extreme acts as urolagnia or other evidences of sexual fetichism are occasionally indulged in by the victim of the hysterical psychosis, and if episodic and not connected with a delusional complex these need not be of grave import. These disgusting symptoms, however, must be differentiated from the defilement that accompanies ordinary acute mania or dementia.

Besides the delirium of major hysteria we are to recognize the bizarre condition of double consciousness, dream states, and occasionally the stuporous phases which cannot be mistaken for those of melancholia or dementia precox. Besides these there are hysteroepileptic and hysterocataleptic syndromes.

Obsessions are not uncommon features of the hysterical psychoses, and I have seen this conjunction in traumatic cases when there has been a syndrome of convulsion, sensory stigmata, globus, aphonia, vomiting, and amenorrhea. In a case reported elsewhere[9] the patient, who had had a fall in an elevator from a short distance without any physical injury, developed an hysterical psychosis. This was expressed in exteriorized hallucinations of vision and smell. She saw the "figure of a man in black who laughed at her" but recognized this as a phantasm. She had an obsession that she was to kill her husband and her child, which she resisted with difficulty. Her sleep was disturbed and she had torturing dreams. For a time she was melancholic. This was accompanied by prolonged ill health. Though her action against the accident insurance company was settled, she did not improve for a long time after.

Conceding the irregularity of hysteria, both as to its development and indefiniteness, it cannot be gainsaid that it figures extensively in many of the well understood insanities—dementia precox especially. The subject of a classic psychosis does not continuously or at all times present the strictly conventional picture of the particular insanity. During the course of her derangement she may for a variable time be apparently confused, and again quite rational, performing some habitual and normal act in a conventional manner. For hours or days she may be apparently herself, or there may be a stranger mixture of orderly and disorderly conduct, variations of the affective element and the existence of intensified moods, conditions of negativism, opposition, caprice, confusion, and violent excitement. In cases where there is a larvated sexual element it may find expression in appropriate reference. In such examples we may detect an admixture of hysteria; some of the irregular degenerative cases are doubtless instances of Kraepelin's disease.

Clouston[10] was evidently the first person to recognize that hysteria might often be closely related to dementia precox, or adolescent insanity, as it was then called. In 1891 in referring to their developmental nature and late appearance he said "in this respect the two diseases show their kinship," and later he added, "the psychological relations of hysteria have not at all received the attention they merit. There are some cases of hysteria that are neither more nor less than mental cases in nine-tenths of their symptoms. The relationship of hysteria to the other neuroses of development is very constant hereditarily and in the same person at different times of life."

Students of modern psychiatry must deplore the differences of opinion that have led to the confusion regarding not only the dementing psychoses, but their relation to the several psychoneuroses with which they are often associated. It is refreshing to turn to Clouston after struggling with the theories of Meynert, Westphall, Delasiauve, Kraepelin, and others in our attempt to harmonize them. Amentia, primary dementia, adolescent insanity, confusional insanity, and dementia precox are all terms that express a deteriorating psychosis having many symptoms in common, but their appearance depending upon the stage of the particular case. Bianchi[11] is inclined to group all these disorders under the term *sensory insanity* and in speaking of them says, "they represent also a changeable phase, a chronological feature of a complex psychosis. Now these syndromes which represent a part of a morbid picture cannot rise to the dignity of psychopathic figures by themselves. They must be framed in a picture which includes them all."

The false paranoid state of hysterical type is

often nothing more than the semi persecutory ideas which originate in patients because they do not believe that the hypochondriacal complaints and the alleged importance of the ailment are fully appreciated by those about them. Sometimes illusions or hallucinations which are the outgrowth of perverted cutaneous sensation or sexual dysesthesia lead to delusions or the latter may be of remote origin and is sometimes associated with convulsions and other symptoms of major hysteria. While such patients are often maniacal, the elation is not continued nor does it resemble true symptomatic mania. It is often of rather precipitate appearance and is rarely preceded by depression. Visual hallucinations are common and the contents of the confused delusions have usually a religious or erotic color.

M. C., girl of seventeen, mother and father psychopathic; family history of epilepsy, dementia, and other psychoses. Patient as child excitable, impulsive, lazy, and spoiled. Was unsocial at times and sulked and masturbated. At boarding school she did not learn easily, gossiped, and made mischief. Late psychoanalysis revealed possible homosexual attachment with no evidence of reciprocity; sexual ideas and self-recrimination. Removed from school late in 1908. To nurse she said she "had done something wrong" that "girls at school thought her pregnant." Worried and cried much; thought she was "growing larger," looked in glass for confirmation and asked nurse whether the latter "*thought it was all imagination.*" When asked why she thought herself pregnant told nurse she had "read something in newspapers." Constant self accusations of wickedness at school. When remonstrated with said, "Why! I guess I'm silly." The mother, a foolish woman, told her she was insane like her cousin, who actually was. Became excited, unreasonable, and would not eat. Removed to a private hospital—very violent, requiring several nurses to restrain her. Could be fed only with difficulty by tube. Tore her clothes and other things. Constantly spoke of being "bad" or "wicked"—much psychomotor activity. In spite of this she would calm down and smile intelligently when seen by strangers, of whom the writer was one. She evidently had more insight than she cared to admit. Taken to "Bloomingdale" November 13, 1908, discharged recovered May 19, 1909. Same disorderly behavior, insomnia, and confusion. *A few days after admission she ate a good dinner voluntarily as she did at another time when it was attractive.* At other times she refused eggs and milk. "She gives very much the effect of a spoiled child as well as of a very sick one." Spoke of being bad, "she had a good and bad side and bad side was getting her into trouble." Said she was afire and her external genital organs were swollen. At times laughs in a frank and open manner. Her confusion is worse at night. When threatened with tube she takes both eggs and milk voluntarily in fair quantities. Complained of maltreatment. Dec. 9.—Greatly improved by the use of wet packs. Patient able to play checkers and talked a little. Three days later excitedly threw herself through a glass door. Psychomotor outburst coincided with approach of menstruation. Dec. 30.—Greatly improved. Makes baskets, dances, in a tantrum tore her waist. Examination made. May 15, 1909.—Showed that she had almost recovered her insight. At one time during November she had for a few days doubtful hallucinations, saying she was lying on glass, and that she saw something running over a towel, that the dishes were moving or talking; that she heard a man call her a "cat," but these were episodical. She does not appear to have been disoriented but obstinate and stubborn, and disinclined to give information which she undoubtedly possessed. Throughout her illness she was whining and complaining, yet could suddenly become apparently quite herself for a time, but soon lacked self-control. She had no delusional reason for refusing food; upon an occasion she mischievously said, "I am dying; I am dead now" and laughed. This was when she was apparently intelligent in other ways. Upon January 10 she wrote a simple though coherent letter to her sister. At one time she complained of feeling "funny," her joints ached, and she felt "choked." Pin points could be felt when applied to forehead. In one of her final communications she made suspicious misstatements, denying simple things she had admitted before which caused Dr. Hoch to observe she "had not the appearance of one who was deliberately lying, yet the whole denial was striking." At one visit I purposely imitated the drawing of a cork from an imaginary bottle. She subsequently reached the incident and said there was a real bottle.

In this case, which was spoken of as one of dementia precox, there was a decided coloring of hysteria and a great deal of exaggeration of her natural traits.*

The so-called hysterical paranoia of Krafft-Ebing is simply the true primary delusional insanity plus the hysterical coloring or the acute derangement that has rapidly grown out of affective disturbances. The ordinary idea of the pathogeny of paranoia is that it depends primarily and alone upon a derangement of judgment and it is the dictum of Hitzig as well as Kraepelin that delusions are due to "imbecility" as well as deranged judgment. Störring[12] says emphatically that there is no imbecility in the early stages of paranoia and insists upon its well-known fact that the powers of judgment may be "above the average in matters unrelated to their delusions." His assumption is that *justifiable* suspisions, unhappiness due to irritable weakness, or frequently repeated emotions ending in persistent moods, lead to the formation of insane delusions. Meynert is quoted by him to the effect that a large number of insane false beliefs are because patients deduce facts from their *own moods* and not moods from *external* conditions as sane men do."

At least during the early formation of insane false beliefs this instability of affectivity is present and the patient is often unable to resist the dominance of the delusions that spring from this cause and the emotional nature of the psychosis becomes apparent. Later the evolution of other fixed ideas in conjunction with the initial delusion marks the real disordered perversion of judgment which signalizes the true paranoia.

Krafft-Ebing in considering the distinctive clinical features of so-called hysterical paranoia, says that the delusions of persecution are the outgrowth of distorted or false interpretation of the patient's will. Known unpleasant subjective impressions, thus the globus, clavus, myodynias and others of the sensory syndrome, result in the creation of delusions of abnormal lightness, the removal of internal organs; visual hallucinations which are so much more common than in true paranoia are followed by delusions in which animals, death, corpses,

*I am indebted to Drs. A. Hoch and Pringle for the use of additional notes.

and play of color are concerned—in fact, all manner of painful sensations from the uterus and pelvic organs are made to do duty as delusions usually of a picturesque and extreme character in which false accusations and pseudologic tales of impossible sexual assault and experience figure.

Miss X, twenty, Hebrew teacher, no history of previous trouble. Mother psychopathic, temperamentally sentimental, musical talent; psychoanalysis reveals no remote sexual embarrassment, yet her manner and conduct show some present erotic erethism. After a slight injury to the lower dorsal region in June, 1910, she suffered great pain, and spinal hyperesthesia, insomnia, restlessness, and subsequent excitability appeared which developed into apparent acute mania. While she was at a summer resort shortly after the trauma her friends noted a change in her conduct and later she showed signs of a pressure of activity; she wanted to play tennis all the time; spoke boastfully of several men who were anxious to marry her. Her activity rapidly increased and she became unmanageable. Spoke of killing father because she feared he would kill her; again, immediately after she would excuse the desire to kill him. Became untidy and threw party masticated food on dishes about. Assaulted nurses and tore clothing.

The patient was taken to a private institution in August in a very excited condition and struggled violently. During the whole time she kept up a continual run of disconnected utterances. When visited by the physician she showed much psychomotor activity. Talked constantly, was playful in conduct, elated in spirits, laughing frequently. She was very alert, but her attention could not be obtained for more than an instant. There was a marked tendency to distractability. During the physical examination she would frequently make remarks relative to doctors and her health. Replies were irrelevant and frequently facetious. She pretended not to know my identity. There was a moderate degree of clouding of consciousness and tube feeding was resorted to in order to maintain nutrition. For two months following admission the psychomotor activity kept up. About the latter part of October she showed for a time less activity and was quiet enough to answer relevantly, showing that she had a correct idea of her environment, and made repeated requests to go to the city to see her people. A day or two later she received a visit from her father, following which she again became active.

Following this lucid period she had others, during some of which she was visited by her friends. These periods were usually of short duration and passed abruptly into a recurrence of the excitement. About the middle of January, six months after admission, she again became quiet, took more interest in herself and her surroundings, and developed insight which she did not have at any of the other lucid periods, and was very reasonable and willing to cooperate in the treatment of her case. During her entire treatment, in spite of her conduct, she had a much more full insight than was superficially apparent and could be pinned down to orderly response although she would instantly indulge in disorderly mischievous excesses and would at times adopt purposive suggestions to betray herself. The contents of her hallucinations and her verbigeration, could also be easily changed by outside influence. Even while in an apparent state of violent excitement and markedly incoherent she would indite absolutely sane letters to her parents. They were well written and expressed, but after they were dispatched she would again within a short time indulge in all her disorderly acts. It was impossible by psychoanalysis to detect a hidden sexual starting point.

This case was diagnosed as a phase of manic-depressive insanity, but the hysterical element was always present. She has, since her discharge about a year ago, shown no fresh symptoms.*

The combination of hysteria and epilepsy was very fully discussed by Charcot and his school from the clinical standpoint.[13] Since the mechanism of the psychoneuroses has been studied systematically by others it has been held that true epilepsy is never of psychogenetic origin but that many kinds of epileptiform convulsions which have been looked upon as examples of the veritable mal caducens are in reality symptoms of major hysteria. It has even been admitted that these spurious fits may present all the symptoms of epilepsy "from fixed pupils to sphincter relaxation," but that tongue biting never occurs. While this is ordinarily true there are exceptions, and I think the time has come when we cannot look upon this symptom as pathognomonic, but the result only of suddenly exerted local violence incident to a severe fit of any kind.† The true test of real epilepsy seems to be as Frink[14] points out that psychotherapeutic measures are inefficient in controlling the true fits, which is not the case where they are due to psychogenetic causation. Spiller[15] refers to the resemblance of certain attacks of this kind to true psychic epilepsy.

When the element of hysteria and instability exist there are apt to be *accès* of psychotic disorder.

A case of this kind of more than ordinary interest came under the care of the writer in 1906. The patient was a dissipated, energetic man of about forty-five, a promoter and speculator who was addicted to venery, but had had no resulting infection. His conversation was apt to be salacious and at times boastful. He was restless, talked quickly, and in an exaggerated manner. There were no evidences of any disease whatever except a certain amount of arteriosclerosis and a rather slow pulse, which at night approached a true brachycardia. His wife stated that he would, apparently when asleep and dreaming, awake, sit up, and excitedly repeat a filthy erotic sentence, but would when verbally soothed fall asleep again. This would sometimes occur several times at night, and the formula would be the same, not only upon the particular night but upon succeeding occasions. The morning after he would be oblivious of what had occurred, or at best have a hazy recollection.

Bromides and rest did some good, but the phenomena were repeated. For some time he disappeared, but in the summer of 1911 I saw him again and found that upon two or three occasions he had bitten his tongue, and had had severe attacks of grand mal. Dr. Foster Kennedy, who saw him, was unable to find any objective signs of brain mischief, and the Wassermann examination was negative. The same attacks expressed by salacious repetition were present even upon the night in which the major attacks occurred. During the day time he was perfectly normal, conducted his busi-

*I am indebted to Dr. W. S. Browne of Sanford Hall, Flushing, N. Y., for records of this case.

†For many years Schroeder Van der Kolk and his school regarded this symptom as definitely indicative of a lesion of the floor of the fourth ventricle.

ness without trouble, and never had an attack of any kind.

It was my idea in the beginning that he suffered from one of the irregular forms of petit mal first detected by Hughlings Jackson, but the conclusion was later forced upon me that the curious erotic states were the residual effects of interrupted dreams of a lascivious character in which the same content existed. There was no need for psychoanalysis for there was nothing concealed. Hygienic treatment, discipline, watching, and psychotherapy effected a disappearance of the major attacks and decidedly diminished the lesser, but there is little chance for permanent improvement because of his dissipated mode of life.

The Obsessional Psychoses.—A simple example of what scarcely exceeds a physiological departure is the tendency many healthy people have to doubt or question the final accomplishment of a volitional act, and which prompts them to try the gas cock, or to open letters closed and directed by them, lest a mistake has been made. More grave and besetting doubts may arise, influencing conduct, bringing misery, and leading to coercive ideas* (Zwangvorstellung) which it is difficult to disobey. Possibly they do not at first pass the border line of introspection, but lead to self catechising and speculation regarding the question of infinity, or metaphysical or religious questioning.

The subject may express his fear of contamination or dirt (mysophobia) which leads him to wash his hands freuently, the fear of open space (agoraphobia), compelling ideas that force him to count or repeat words (arithmomania, onomatomania), to touch objects in his daily walk (delire du toucher), to avoid crowded halls or confined spaces (claustrophobia).†

The more serious manifestations of this kind of psychasthenia occasionally find vent in obsessions to steal (kleptomania), to set fire (pyromania), and in compelling impulses to drink (dipsomania), while sexual obsessions may lead the victim to commit perverted acts, especially in conjunction with the latter. Again the sight of a sharp weapon may possibly lead to the impulsive commission of a crime of violence.‡ All these forms of mental weakness do not strictly come under the head of insanity because the subject knows the nature of his obsessions and their absurdity, yet he is unable to fully escape their influence.

According to Westphall these besetting ideas "enter into the foreground of consciousness against and despite a man's will. It is important to drive them away. They impede and thwart the normal train of ideas, and their victim inwardly recognizes that they are abnormal and foreign to him and confronts them with sane consciousness."

Störring in commenting upon this writer's conclusion says "that the characteristics emphasized by Westphall, are, first, the mental coercion with which the ideas are forced upon consciousness. Second, the consequent derangement of the train of ideas, and lastly the subjective consciousness of abnormality.

With this there is always much anxiety, and strain—sensations that may lead to serious consequences so far as the genesis of actual insanity is concerned. This anxiety is, as a rule, a result of the obsession, no matter what may be its nature.

In rare cases these forms of obsession may be so aggravated that they finally assume the appearance of a grave psychosis; in fact, they are practically the expression of degeneracy that may find expression in other ways. Delusions and hallucinations and complex mental disorganization may then actually be present. Coercive ideas may, therefore, become absolute insane delusions, and according to Friedman this is the case when they give rise to an established judgment of reality, and such permanency and false realization are due to extreme anxiety rather than intensity of the idea. When this point is passed and the unreality is unperceived or accepted, the patient, being unable to analyze it or know that he has passed the borderline, is really insane.

A case which closely approached this point is that of J. V., fifty years, capitalist. Nothing of moment in his history. Comes from healthy stock, no previous bad habits. In April, 1908, he consulted me about his condition of extreme distress caused by coercive ideas which compelled him constantly to examine coal hole covers as to their safety. He was obliged in his walks to test all those he went by, trying to lift them with the toe of his shoe. He also was obsessed with the idea that he had misdirected letters and had compromised himself by writing his business affairs to the wrong parties. This caused great suffering and anxiety, insomnia, and fear of consequences. By means of psychotherapy consisting of mild assurances and elucidation, and the internal administration of the glycerophosphates he recovered entirely and went to his home in a remote city. Toward the end of 1908, as the result of hard work incident to the participation in fresh ventures, he again became a wakeful, irritable invalid and consulted a physician who injected gonococcic serum with the idea that certain joint pains were of gonorrheic origin, although he had never had this disease and was a man of unexceptional morals. The results were disastrous; he again became obsessed, slept but little, ate irregularly, and took insufficient food. He was so distracted that he could not follow his business. At this time coercive doubts dominated him to a great degree. He was so strongly convinced that he might have written offensive letters to others or compromised himself, that he would allow no one to empty his waste basket, but even after opening letters and examining them he would tear them up, but after office hours would piece together the scraps in his basket to assure himself again that he had not committed a blunder. He finally would not write but resorted entirely to the typewriter—even then his clerk had to open the letters. When he went home he picked up pieces of paper in the streets to see if some bit of his correspondence had not gone adrift. Upon an occasion after retiring he looked out of his window and saw a paper attached to the fence and fluttering in the wind. He arose in the middle of the night and detached it to find out its contents. About February, 1909, he came to me suffering intensely from his indecision. He was then accompanied by his

*Du Fursac divides them into *intellectual*, in which there is a voluntary reaction, and *inhibitory*, when abulia results, but this division is perhaps too arbitrary, as there are many exceptions. To the former belong the persistent ideas of unreality non existent doubts about eternity, neglected duties, and conscientious scruples.

†Janet describes no less than five kinds of obsession, with thirty-three subdivisions, three mental manias, with twenty-four subdivisions. ("Les Obsessions et la Psychasthenie." Paris, 1903.)

‡Freud says these ideas "have for their source dissatisfaction with their marriage and the fear of seductive thoughts of sexual nature."

brother, whom he kept with him constantly, fearing that he might write some letter. When asked what the insulting contents of the letters might be his replies were indicative of the existence of mild delusions regarding his own chastity with some mention of suicide as a means of escape. Psychotherapy and a trip to Europe in company with the brother and abstinence from all business gradually effected a cure and his subsequent marriage to a sensible woman made it complete. In a letter dated October 7, 1911, he said he was then happy and busy.

In this case the anxiety was rapidly leading to the fixation of the dominating idea, and it is conceivable how a true delusional psychosis could have developed.

The disposition has been to look upon all these cases as examples of simple psychasthenia, when in reality their derangement is often but the beginning of something far more serious. When we take into account the fact that certain mental disorders with limited delusions have with this a common form of origin in heredity and temperamental predisposing influence, it is not difficult to account for the ultimate trend of some obsessional disorders. The same weakness of makeup which, for instance, conduces to dementia precox may simply find expression in hysterical or obsessional states, in fact, dementia precox is sometimes symptomatized by striking obsessions.

Brief notes of two cases will illustrate what is meant.

E. J., a youth of eighteen, parents ignorant and neurotic. As a boy had chorea and minor infantile diseases. He is physically badly developed, is oxycephalic and has Morel's ears. Always timid and "nervous," slept badly and dreamed a great deal. Onanist, dull at school, and very ignorant. At puberty he became shy, retiring, and afterward conceited. Dressed conspicuously, constantly quarreled with schoolmates, and developed the morbid idea that they were inimical to him and envious of him. Obsessions developed that he was contaminated by one of them, and that the ash of a cigarette that had entered his eye had communicated syphilis. He had to be reasoned with constantly and came to my house at all hours, day and night. He was grandiloquent in conversation and vain—boasted of his strength and claimed that women generally admired him. At other times was introspective and indulged in doubts as to reality. He was very irresolute and would avoid previous engagements because of some immeasurable fear of danger. For days at a time he would not exert himself and there was a lack of initiative. His conversation was silly and he was without ambition or purpose, his only apparent mental energy being shown in begging, Dr. G. de F. Smith, and myself, to assure him of the fact that he had not contracted syphilis.

This case is one where the psychasthenia has extended to the point of hallucinative formation and clouding of consciousness.

A. M. L., seventeen, father eccentric, mother's family psychopathic, maternal grandfather a spiritualist and "crank," mother's brother a "free lover," patient's mother and sister psychasthenic: both have obsessions with doubts and fears. No alcoholism. Patient graduated from high school. Father says he is industrious but this is doubtful. Was an onanist, but no special introspection growing therefrom, although he refers to the immorality of his boyish associates and was evidently a party to their transgressions. For some years presented arithomomania, persistently counting to sixteen; facial tic consisting of double blepharospasm. Has for months been obsessed to count fence posts and railroad ties. When he reached school he would turn back to count trees that he had passed, and then on returning lie and invent an excuse for his truancy; fear of "going to town" so that he remained much at home in the society of his obsessed family. Periods of mysophobia. When he got into bed would arise eight or ten times thinking he had "got in on the wrong side."

Would say something was missing from his dress that ought to be there, and would constantly turn about in front of the mirror and ask his mother and sister to inspect him. After repeated assurances would repeat the performance. During past few months has been retiring, preferring his own society. Said that in a low part of the city he saw people he knew (who were really not there), in windows who spoke to him. He felt embarrassed and said, "How could people sit and look out of the window, particularly people whom I knew ought to be elsewhere, and I had to think them back where they belonged." When he went home he said "how could these people live in such places?" and he strove to adjust his ideas by saying "they have to live there because the rent is cheap."

These hallucinations were constant, and though he knew he was mistaken, he could not be fully reassured. His manner is restive and of late he has not attended to his work, but has worried a great deal. He is also troubled by insomnia and is kept awake by onomatomanic obsessions which compel him to say, *"Oh! Oh, dear! Dear! Oh!"* etc.

The importance of coercive ideas which constitute so-called kleptomania, pyromania, dipsomania, and other impulsive acts are not always recognized as pathological evidences and one of them is often ridiculed by the press and public. Much interest therefore is attached to those obsessions which lead to the commission of crime and to the defense of responsibility of the subject, and their real nature should be better understood. While the defendant in such cases probably knows the difference between right and wrong which is the test applied by the courts, he belongs to the class of those who have pathological obsessions that at the time destroy the power of distinction and interfere with the choice, as they destroy the free exercise of the will. Wharton and Stillé[16] refer to the opinion of Justice Somerville[17] who held "that a man is never responsible, if, by reason of duress of mental disease, he has so far lost power to choose between right and wrong as not to be able to avoid doing the act, so that his free agency was at the time destroyed, and at the same time the crime was so connected with such mental disease in the relation of cause and effect as to have been the product or offering of it solely."

The Freudian explanation of many obsessional states which is in the main correct, does not, I think, bear out the application he makes. His reference to the sexual reminiscences seem too narrow. Thus, for instance, the mysophobic obsessions are said to imply moral "uncleanliness," while the compelling impulse to pick up fragments of paper is ascribed in one case to the latent memory of a clandestine love correspondence. Too many of the patients of the first class actually refer to the fear of contamination of dirt or disease, while in the case of J. V., which is one of the second class, no

sexual coloring or hidden trauma whatever were found. Freud also accounts for agoraphobic obsessions as engendered by the fear of dizziness connected with a neurasthenic state which seems to be equally far fetched. The hypochondriacal expressions of the introspective masturbator are, of course, sometimes manifested in reactions springing from his sense of hidden shame and depressed state.

The prognosis of the minor mental derangements to which reference has been made is by no means as good as might be at first supposed from their apparent simple functional nature, for there is too often an underlying constitutional weakness, which may be traced back to alcoholism or insanity in other generations. Obsessional conditions especially, are more frequently found in people with alcoholic parents. Perhaps in some the particular compulsive idea is really the outgrowth of a disturbance of emotional life dependent upon the theory that "the sexual excitement which is kept away from consciousness produces physiological effects which are the substratum of the feelings of distress or anxiety."

There seems to be an arbitrary agreement among the latter-day psychiatrists that the *ipse dixit* of the psychoanalyst must be really the last word.

Admitting the value of Freud's theories and methods, and those as well of Dubois and others, there are many cases where psychotherapy fails utterly, and some of the apparent cures are but temporary. The hysteric habit, if such a term can be used, is too deep seated for its uprooting, even though the physician is able by catechism to lay bare a hidden trauma, or to correct and apparently regulate the disordered mental operations arising therefrom. It must be the experience of many that after patient work extending sometimes over months or years, there is a goodly number of cases that do not pass a certain point of improvement. On the other hand, brilliant results may follow two or three seances, the patient being reassured and comforted. Temperamental influences always handicap the efforts of the most conscientious and painstaking psychotherapeutists, and the "catharsis" which is supposed to turn out the offending sexual ideas does not take place.

The method of substituting a healthy train of ideas or a new picture to supplant the old and offensive one, is the procedure followed by Dubois, Janet, the late Russell Sturgis, Putnam, and others, the besetting complex being ultimately eradicated; but it must be realized at the same time that there is no kind of psychotherapy suited to every case.

The radical teachings of Freud have borne fruit and the extremes to which he and his disciples have gone would suggest that nearly everyone is blighted by some corrupt sexual experience and that really no one is pure. Patients are said to be homosexual and perverted, and reports of this kind of psychoanalysis with salacious details stare one in the face from the pages of many contemporaneous medical journals. Freud himself would make us believe that even incest is not an unusual occurrence, for he has applied the name of Œdipus to a particular complex which is a form of the anxiety-neurosis. While it is true that occasional disgusting experiences in the life of a psychasthenic subject are stirred up, there is, I am convinced, great exaggeration.

It is encouraging to find notable exceptions to the sexual school. Briquet, the greatest writer upon the subject in his time and perhaps any other, had no difficulty in discovering causes, while in our own time many cases have been investigated by psychoanalytic methods without any hidden erotic concepts. J. J. Putnam and Linenthal and Taylor of Boston[18] have reported six cases where no "revolting idea" was unearthed, although "a love affair which had a distressing outcome" accounted for the psychoneurosis in one woman. In all the others, falls, worry, and mental perturbation of other kinds were the causes of the disorder.

There is nothing strictly new in psychotherapy, or anything unfamiliar to scores of experienced medical men who have for decades used suggestion and substitution, and who certainly have not been conscientious practitioners if they have not thoroughly delved for every possible factor and every disturbing influence in the patient's life. It is not always necessary to hypnotize the subject to accomplish results—though it is possible sometimes in this way to get at reminiscences that enter into the formation of the psychotic state. By this means the author many years ago systematically made diagnoses which were apparently impossible by simple interrogation, and was able to substitute fresh ideas and give assurance.[19]

These cases are so different that it is difficult to lay down any special directions. So far as psychotherapy is concerned we must be governed by the indications of the particular case. It is not only important sometimes to bring the victim face to face with the concealed ideas which have led to his instability and irresolution, but he should be taught self-control, and be made when he does so to feel the satisfaction of *knowing* he has conquered at least for a time. Surrender is conducive to a continuance of his disorder. Should change and isolation be indicated they will do much for some cases; the same may be said for the provision of all absorbing and non-fatiguing occupation. Before closing, I wish to reiterate a word of warning against the ill-judged use of methods of psychoanalysis which stir up erotic and unclean ideas in women who at best cannot profit by sexual excitement, and who are often so unstable and defective as to be beyond the reach of medical skill.

PROMINENT EARS.*

By ROBERT T. MORRIS, M.D.

NEW YORK,

PROFESSOR IN SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

PROMINENT external ears may deflect currents of cold air against a delicate drum membrane. Discomfort or even danger from this source of irritation on windy days will make it desirable to change the "set" of certain ears. The subject has not received quite as much attention as it seems to deserve, because surgeons of standing do not quite like to operate for the purpose of obtaining cosmetic effects only. It is somewhat beneath their dignity to assume the responsibility of subjecting a patient to operation excepting in matters relating to life or utility of the individual, and the resetting of ears would on first thought be classified among cosmetic operations, to which surgeons are instinctively rather averse.

A good deal of mental suffering is really caused sensitive people when they attract the direct gaze of children whose interest finds a target in some defect. Dr. Keen allowed competent surgeons to take charge of the subject of removing moles, when he pointed out the tendency of some moles to undergo malignant degeneration.

The danger from deflection of currents of cold air into the ear should make us give serious consideration to the matter of resetting prominent external ears, even though we might be averse to doing

Fig. 1.—M. F., before operation.

the work on cosmetic grounds alone, or for the mental relief of people who found their ears an object of attention by children in the street car.

One reason why prominent ears have not been set back more frequently is perhaps because of an operation sometimes done which consists in simply excising an ellipse of skin from ear and scalp and suturing the margins together without excising cartilage. Elastic fibrocartilage exerting ceaseless traction upon sutured skin has a tendency to gradually cause recurrence of the original deformity.

For many years I have preferred the method of excising practically all the fibrocartilage of the

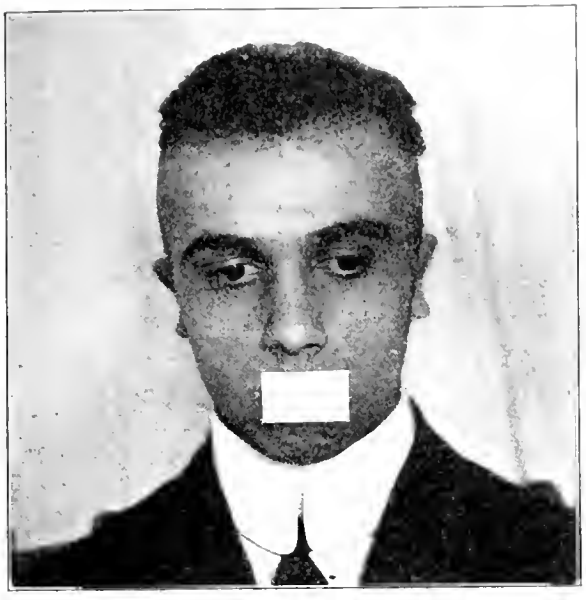

Fig. 2.—M. F., after operation.

concha, antihelix, and antitragus. As a preliminary step an ellipse of skin is removed from the posterior part of the ear and from the mastoid region of the scalp. The ellipse is of such shape that about one-half relates to the ear and the other half to the mastoid region of the scalp.

It is best to press the ear flat against the mastoid region before determining upon the lines for incision. The ear is then grasped by the helix, drawn well forward, and the ellipse of skin snipped away with a pair of curved scissors, leaving subcutaneous structures as nearly intact as possible. The blood supply to the ear is large, and commonly requires ligation of branches of the posterior auricular and superficial temporal arteries. This ligation is best done with catgut threaded in a needle, rather than with artery forceps.

Use a pair of small but strong curved scissors for outlining the cartilage to be removed, and then gradually trim the cartilage away from the skin of the anterior aspect of the ear by alternately pressing and snipping.

The skin from which cartilage is removed is thin, but well supplied with blood, and does not slough subsequently. The very thin skin over concha and antihelix may be buttonholed at one or more points while cartilage is being removed, but this is desirable, and if one is so dexterous in technique as wholly to avoid buttonholing the skin he must purposely make one or more openings through it later for purposes of drainage. This constitutes a feature of prime importance in the operation, perhaps the most important single point in technique relating to the entire operation. The reason is this: When the ear, shorn of cartilage, is sutured back over the mastoid region, the space from which cartilage was removed has a tendency to fill with blood clot. Blood clot collecting beneath this thin skin may lead to failure of union or to

*Cases reported at the Clinical Society of the New York Post-Graduate Hospital, March 15, 1912.

sepsis. If, on the other hand, the skin is buttonholed, purposely or accidentally, blood promptly escapes upon the dressings, and we have no damming or pocketing of clot.

Another feature of consequence in the operation, small but important, relates to management of the external auditory meatus. This should be plugged

Fig. 3.—Dr. B., after operation.

with absorbent cotton in advance of operation; otherwise blood may enter the meatus and form a troublesome clot upon the drum membrane. Neat application of the dressing is very important. After suturing skin margins of ear to skin margins of scalp two thicknesses of iodoform gauze cut to the shape of the wound line are nicely fitted between skin of helix and skin of scalp. Iodoform gauze is daintily packed upon the skin of the anterior part of the ear with attention to depressions, and to the fossa of the helix, compressing the skin evenly and nicely, so that blood cannot collect beneath it. We then have practically a skin graft with tendency to form immediate union.

Gauze must not be packed into the meatus. Leave the meatus open, or loosely covered with gauze. Failure of primary union has occurred but twice among my cases, and in these cases, when granulation appeared, secondary adhesion was obtained without difficulty.

The chief danger from the operation, which I have anticipated but have not seen developed, is perichondritis of the cartilage remaining in the helix. This perichondritis, which is familiar to us in the ears of athletes, I assume might appear after operation. It would be well to keep this point in mind, at any rate.

The two patients whom I show this evening are M. F., who entered the hospital in February, and Dr. B., who entered a month or so previously. They were not confined to bed by their operations, but remained at the hospital for a few days to have the dressings looked after properly. The photographs of M. F. give a full front view before and after operation; the photograph of Dr. B. from behind shows that helix and lobe are the only parts of the ear allowed to remain free after suturing.

MALFORMATION OF TAENIA SAGINATA (T. triedre).

By G. A. MacCALLUM, M.D.,

NEW YORK.

The unusual specimen herein described had as its host a woman in Canada who recently consulted Dr. L. Morden of Brooklyn, and through whose courtesy we are allowed to report it.

The specimen is shown in Fig. 1 and is of the form of *Taenia saginata* known to the French as *Tenias triedres, triquetres, or prismatiques* and considered a monstrosity. While this particular abnormal form of *Taenia saginata* or beef tapeworm is rare, yet it has been frequently reported in Europe. Blanchard, Cobbold, Leuckart, Neumann, Coats, Braun, and many others have reported its occurrence, but as far as our opportunity for reference goes we do not find it reported in American literature, hence this record.

Taenia saginata, as is well known, is probably more prone to malformation than any other of the cestodes, but why this should be so is not known. Some helminthologists have gone so far as to suggest that this particular form should rank as a species. For instance, Brera named it *T. hybrida*, Kuchenmeister *T. capensis*, and Cobbold *T. lophosoma*. However, it is now considered that, notwithstanding its abnormalities in form, they all belong to the one species, *T. saginata* or beef taenia.

In this particular malformation the individual at once suggests the partial fusion of two worms. As may be seen in Fig. 1, the body presents itself in the form of three leaves or folds, a cross section of which shows the bifurcated appearance. Writers describe the scolex as fused also, being larger and presenting six suckers instead of four as in the normal head.

The cross section of the body in Fig. 2 shows it to be bifurcated, the longer and thicker leaf being divided into two, and the line of division on the surface being shown on each side by a shallow groove. Each proglottis shows plainly the genital

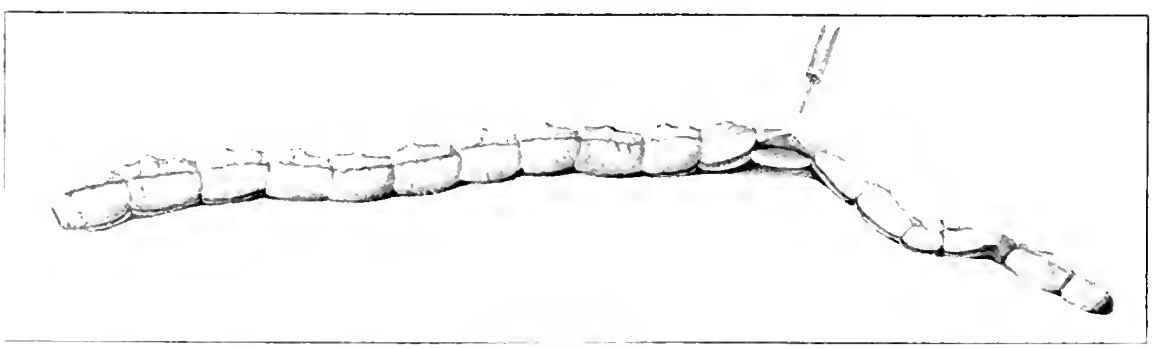

Fig. 1.—Sketch of malformed Taenia showing lateral splitting of segments.

aperture at the center of the edge of the undivided portion, and from it the reproductive organs may be easily traced and located chiefly in the thicker portion of the segment, although, as will be seen by the plate, some folds of the uterus and some of the testes occupy the middle of the whole length of the bifurcating leaves or folds. Again the water vascular canal is quite large in the thicker fold but exceedingly small in each of the others. Although the worm may represent the fusion of two individuals, there is no trace of two sets of organs.

Fig. 2.—Transverse section of segment of malformed Taenia saginata showing: A, Cirrhus; B and E, Water vascular channels; C, Uterus with eggs; D, Lobule of testis; F, Vagina near which are portions of the vas deferens.

PEDIATRIC MEMORANDA.

ATYPICAL INCIPIENT POLIOMYELITIS AND ITS DIAGNOSTIC DIFFICULTIES.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

A DECADE or two ago the diagnosis of acute poliomyelitis called for no extraordinary skill. At that time the poliomyelitis producing microorganism was supposed very rarely to venture beyond the area of the anterior gray horns of the spinal cord and, accordingly, the paralysis was apparently limited to the extremities. So rarely did the old authors find involvement of other parts of the body that Gowers,* for example, deemed it important to emphasize that on one ocasion he had observed unilateral paralysis of the face. Evidently the disease has since undergone many and material changes. It is now fully established that the poliomyelitic inflammatory process often extends also to the posterior horns of the cord, the medulla, pons, cerebellum, cerebri cura, and meninges, giving rise to complex clinical pictures which in their incipiency lead to gross diagnostic errors.

Poliomyelitis Affecting the Face, Abdomen, Spine, and Extremities; Resembling Encephalitis.—The twenty-months-old girl, born of healthy German parents, and apparently in the best of health, was suddenly seized with violent vomiting and general bodily pain. After administering a dose of castor oil and a soap-suds enema, the vomiting partly subsided, but the child passed a very restless night, twitching, tossing, and talking and crying from pain. I saw her in the morning. She was in a state of partial stupor, her head was slightly retracted, her neck stiff, her body, except for occasional twitching, motionless and her eyes rolling upward between the half-closed lids. Her temperature was 103° F. per rectum. On careful examination I noticed that the whole right side of the body, including the face, was paralyzed. The face was drawn to the left side, the lower lip drooped and on pulling the tongue forward the patient seemed to experience considerable difficulty to draw it back into the mouth. As the clinical picture remained unchanged in the afternoon, I felt quite certain that the child was suffering from acute encephalitis, possibly of grippal origin. I was not a little surprised, however, when I found the next morning that the paralysis had extended to the left forearm and the abdominal and spinal muscles (see Fig. 1); that the general rigidity had subsided, and that the right patellar reflex was abolished. The case was, of course, very clear thereafter. I was evidently dealing with poliomyelitis involving the pons, medulla, and the anterior and posterior horns of the spinal cord. In hospital practice the diagnosis could, perhaps, be facilitated by an examination of the blood and cerebrospinal fluid, which in poliomyelitis shows a marked diminution in the number of leucocytes (3500) in the blood, and an increase of lymphocytes and protein matter in the cerebrospinal fluid. In private practice, however, these data are rarely available, since by the time the results of the examination are obtained, the diagnosis can usually be made from the subsequently developing new symptoms or recession of the paralysis. The prevalence of the disease in epidemic form occasionaly serves well to elucidate obscure cases, especially when there is a history of direct exposure to infection (as it occurred in cases 4 and 5). On the other hand, epidemicity is also apt to cloud our judgment and lead to "snap" diagnoses—many other brain and cord affections or convulsions from various causes helping to swell the statistics of genuine poliomyelitis.

Poliomyelitis Affecting the Left Muscles of the Neck, Shoulder, and Tongue; Resembling Men-

*Diseases of the Nervous System, Vol. I, 1893.

gitis. This case, a robust girl four years old, came under the observation of Dr. J. L. Rubinstein. The child was apparently perfectly well up to two days before. At that time she complained of a sore throat which the doctor thought was due to the grip. The following day she complained of

Fig. 1.

severe headache, and toward evening began to vomit. The attending physician having been busy with other cases, Dr. M. Krakowski was hastily summoned instead. He found the patient in semicoma, delirious, with a temperature of 104° F., head strongly retracted, Kernig's sign marked and her whole appearance that of a case of meningitis. The next morning, through the courtesy of Dr. Rubinstein, I had the opportunity to see the case with him as well as Dr. Krakowski. On mere inspection, noting the peculiar "paralytic attitude" of the body, I surmised that the child was suffering from poliomyelitis, but after carefully examining the patient, I very much hesitated to express a positive opinion. I found her in a moderate stupor, from which she could be roused when talked to firmly; the neck was stiff, and when the head was flexed downward toward the sternum there was concomitant flexion of the legs upon the abdomen (Brudzinski's sign), slightly exaggerated patellar reflexes, slight Kernig's sign; delayed pupillary reaction and rolling of the eyes upward and sideways, and distinct *Taches cerebrales.* I found, however, that the cerebrospinal fluid escaped very leisurely, and was serous in character. After discussing all the diagnostic possibilities, I concluded that we were probably dealing with polioencephalitis and suggested to wait for further developments. As there was but slight improvement in the child's condition the following day, the parents decided to consult their previous family physician, a gentleman of large experience. This doctor unhesitatingly pronounced the case as meningitis and advised to have the patient at once sent to the hospital, in order to enable them to employ Flexner's meningococcic serum—before it was too late. The child was transferred to Lebanon Hospital. To my great surprise I learned a few days later that there was supposed to be absolutely nothing the matter with the little girl and that she probably had suffered from a slight attack of the grip. However, when about two weeks later the child had returned from the hospital she was unable to rotate her head to the left side; her upper arm was partially paralyzed and on protruding the tongue it would deviate to the right side. The poliomyelitis apparently became localized in the left medulla and upper cervical region.

Poliomyelitis Affecting the Superficial and Deep Muscles of the Neck and Extremities; Resembling Polyneuritis.—The little girl was three years old, delicate from birth and subject to frequent "colds and coughs," apparently due to enlarged tonsils and adenoids. She had not been feeling well for two days, as the parents put it, "was terribly weak, had pain in swallowing, and refused to take any nourishment." As I went about to examine her she cried bitterly with pain. I was informed that on one occasion a mouthful of water came back through the nose. The throat was free from a deposit, but deglutition was difficult nevertheless. Her temperature was only 100° F. She was able to move her legs from one part of the bed to another, but complained of pain while doing it. The same was true of the upper extremities, especially of the hands. She could rotate her head laterally and there was neither retraction nor stiffness of the neck. We thus had: symmetrical paresis of the extremities, intense pain, difficult deglutition, regurgitation of fluids through the nose and nasal

Fig. 2.

tone of voice (which she always had owing to the adenoids)—*i. e.* a typical picture of postdiphtheritic neuritis—and yet no history of diphtheria or of any other grave disease within six weeks previous to this attack. I ordered 3 grains of sodium salicylate and 1 100 grain of strychnine to be given

every three hours. The next day she was entirely free from pain and apparently happy. No longer objecting to the examination, I went over the case most carefully, and as I propped the child up against the pillow to give a real good look at her throat I was surprised to note that her head dropped forward upon the sternum like a dead weight, the patient being unable to lift it in position. On removing the pillow and placing the patient in slanting position, the head dropped also forcibly backward. The accompanying illustration (Fig. 2) was taken about six weeks later. She has gradually greatly improved though she still (four years after the attack) shows lack of strength in the anteroposterior mobility of the head. With all our latest scientific data on the subject, I am not aware of any diagnostic means which would have enabled to differentiate this case from polyneuritis at so early a stage.

Poliomyelitis Affecting the Left Glutei and Abdominal Muscles; Resembling Tuberculous Coxitis.—J. C., two years old, came to the Babies' Hospital Dispensary (Dr. H. E. Hale's division) with the following history: Having been perfectly well up to four days before, he suddenly complained of pain in the legs and seemed to have a slight rise of temperature. The family physician was consulted, but finding no tangible cause for the complaint he administered a laxative and ordered to keep the child in bed for a day or two. The next

Fig. 3.

day the patient was out of bed, but off and on continued to complain of pain, especially in the left leg. It was for this symptom that he was brought under our observation. On examination I found that he was able to make free use of the extremities while in sitting posture and also able to walk, though he did it with reluctance, holding the leg stiff. The child's musculature as a whole was flabby and no perceptible difference could be elicited between the muscles of the different extremities. As pain and a slight limp were at that time the most characteristic symptoms, and as the onset

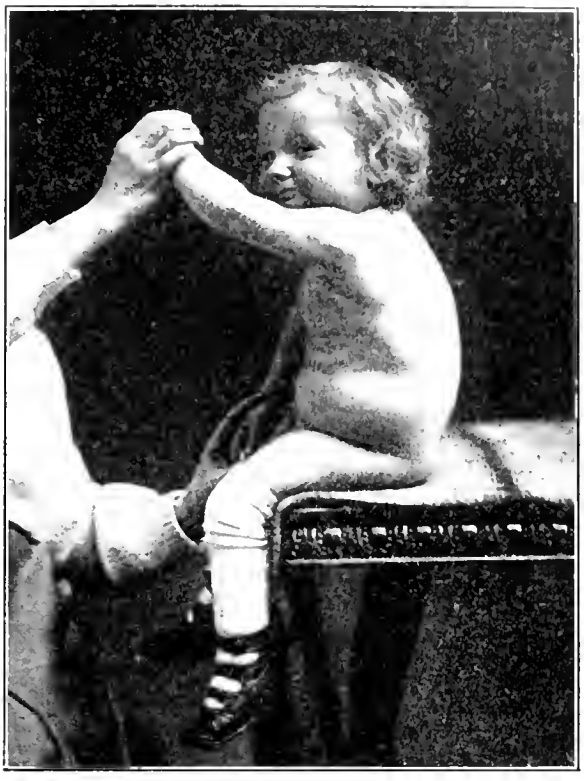

Fig. 4.

and course of the attack were so exceptionally brief, it required quite a stretch of imagination to pronounce the case as poliomyelitis. Indeed, noting also that there was slight asymmetry between the gluteal regions (which later proved to be atrophy of left gluteal muscles), and on further inquiry having learned that the child had recently sustained a fall, I was rather inclined to the belief that the patient might be suffering from incipient coxitis. I could not help thinking also of rheumatism—pain being the predominating factor. However, all speculative theories soon went to naught. On the second visit, one week later, I found the left gluteal muscles distinctly atrophied and the abdominal muscles (see Fig. 3) equally affected. Moreover, a few days later J. R., a little girl seventeen months old, living in the same flat one floor above, was brought to the clinic suffering from complete paralysis of the left leg, except the foot, partial paralysis of the right leg and unilateral paralysis of the abdominal muscles (Fig. 4). This child had the attack of poliomyelitis about two weeks before the aforementioned boy, her playmate.

127 West Eighty-seventh Street.

Worms as a Vehicle of Infection in Cholera.—B. Ghosio believes that worms that live in the water play a large rôle in spreading cholera and typhoid fever. In a certain town the water supply was found to be infected with cholera vibrios, and chemical disinfectants were added to the water until these were no longer found. The water worms were also killed. The author found living cholera vibrios in the dead bodies of the worms. Many of the water worms are migratory and travel a considerable distance through the ground, carrying with them various bacteria, which they may deposit on vegetable matter, especially after rains. This is an important method of disease transmission.—*Il Policlinico.*

PELLAGRA IN THE CANAL ZONE.

By W. E. DEEKS, M.A., M.D.,
ANCON, CANAL ZONE,
CHIEF OF MEDICAL CLINIC, ANCON HOSPITAL.

SINCE the recent awakening of the medical profession to the widespread existence among them of the hitherto almost unknown disease on this continent—pellagra—reports of cases have issued from many parts of the temperate and tropical zones. It will be of interest, therefore, to report, both from an etiological and therapeutical standpoint, the following cases that were admitted to Ancon Hospital. It is not the intention of the author to discuss the different theories at present advocated as to the etiology of the disease, but to briefly draw from the results obtained conclusions which may throw some light on this interesting affliction.

CASE I.—J. W. O., Martiniquan woman; colored; 36 years of age; was admitted to Ancon Hospital June 16, 1910, with acute pellagra. The dermatitis was characteristic on the hands, forearms, and shins, also the mucous membranes of the mouth, rectum, and vagina. She complained of pain in the stomach, also on urination, and was sensitive to pressure over the abdomen. There was a serosanguinolent discharge from the vagina. The parts about the rectum were excoriated. The leucocytes were 10,400 with 65 per cent. polynuclears, 1 per cent. large mononuclears, and 18 per cent. lymphocytes. On admission the temperature was 100.2°, pulse, 128, and respirations, 24. The temperature and toxic conditions increased daily, and she died on the 21st, five days after admission, with a temperature of 107°. Post-mortem: There were found an acute and subacute spinal meningitis, chronic interstitial nephritis, and chronic cholecystitis.

CASE II.—L. D., Martiniquan; colored; male; age, 40; four and one-half years on the Isthmus; was admitted July 13, 1910, complaining of having been sick for eight days, and unable to work because of pain in the joints and extremities. On admission the temperature was 100.4°; pulse, 128, and respirations, 54. Patellar reflexes absent; Romberg's sign present; gait, ataxic; unable to coordinate. He had the characteristic oral mucous membranes, but no dermatitis. From the midday of his admission he vomited almost constantly, was nervous, slept badly, and developed an uncontrollable diarrhea; temperature increased, and he died on the fourteenth day after his admission with a temperature of 106°. His leucocyte count on admission was 11,200; polynuclears, 81 per cent.; large mononuclears, 4 per cent., and small mononuclears, 15 per cent. Post-mortem findings: Acute and chronic ulcerative colitis, proctitis, and lymphadenitis (mesenteric and mescolic), chronic degenerative myocarditis, acute degenerative nephritis, and edema of the lung.

CASE III.—V. C., female; colored; age, 40; from Guadeloupe; was admitted to the hospital June 4, 1911, from Gorgona. She had been three months on the Isthmus. On admission she complained of having been ill twelve days with fever, vomiting, diarrhea, and pain in the back. She had the typical dermatitis on the hands, forearms, and breasts, the red hyperemia of the oral mucous membranes, doughy abdominal skin, vaginitis, and proctitis, with excoriated skin about the perineum. In the vaginal discharges were gonococci. The leucocyte count was 13,000; temperature on admission, 100; pulse, 120; respirations, 36. She died on the fifth day after admission with a temperature of 100.5°. The autopsy showed multiple infarction of the kidneys and spleen, chronic nephritis, acute capillary bronchitis, acute splenitis, chronic adhesive peritonitis, syphilitic cirrhosis, myocarditis, and ulcerative stomatitis, and a general septicemia of undetermined origin.

CASE IV.—S. C., colored; female; Martiniquan; local residence, Culebra; five years on the Isthmus. Was in the Ancon Asylum suffering from paranoid dementia præcox from June 26, 1909, to September 13, 1910. She was discharged at the request of her husband, and was readmitted July 25, 1911, to the medical wards with a temperature of 100.4°; pulse, 128; respirations, 24. Her condition on admission was very critical, almost comatose. The dermatitis on the hands, forearms, and feet was very characteristic, also the acute inflammatory condition of the oral, vaginal, and rectal mucous membranes, with excoriated perineum and inner surfaces of the thighs. Her stools contained the ova of uncinaria and ascaris, with plenty of blood and pus. The urine contained a few hyaline casts; hemoglobin, 90 per cent., and leucocytes, 9,400. There was no diarrhea. At this time, being impressed with the similarity of the early symptoms of pellagra, and those of patients who were large consumers of cane sugar and starchy foods, to the exclusion of meats, green vegetables, and fruits, the writer decided to use a special diet in which sugars and starches were absolutely excluded. The patient was given a diet of orange juice, milk, meat broth, and eggs, and the only medication was dilute nitric acid, 20 to 30 drops, three times daily in one-half glass of water on an empty stomach. An occasional dose of castor oil was also administered. Improvement in her physical condition was marked after the first two or three days, and in three weeks the dermatitis had practically disappeared, leaving a clear skin with only slight pigmentation. All the mucous membranes became perfectly normal, and physically the patient could be considered well. As her strength returned her mental symptoms became worse, and on the 22d of August, about a month after admission, she was transferred to the asylum in a maniacal condition. She died September 3, twelve days later, and post-mortem findings revealed only a slight diffuse nephritis with a moderate acute degenerative process superadded, and a slight chronic ulcerative metritis, not enough to account for her death.

CASE V.—G. P., Martiniquan; female; colored; age, 27; six months on the Isthmus; was admitted August 22, 1911, with a temperature of 103°; pulse, 120, and respirations, 32. Her physical examination was negative except for the characteristic stomatitis, vaginitis, and proctitis. She also suffered from pains in the lower extremities and abdomen. There was no dermatitis. Her leucocytes were 17,200. After three weeks of treatment she was discharged practically well.

CASE VI.—M. D., female; colored; age, 33; a native of Trinidad; was admitted from Gorgona on August 23, 1911, with a history of about one month's illness. She complained of some fever, anorexia, abdominal pain, sore mouth and throat, and more recently diarrhea. She had the characteristic intense stomatitis with superadded white exudate, an intense vaginitis, some nephritis, and a diarrhea with plenty of pus and blood in the stool. Her leucocyte count was 11,000. She was put on treatment, and was discharged well on Oc-

tober 21, 1911. She was on admission in a very critical condition, much prostrated, but was able to sit up and move about three weeks after admission.

Case VII.—J. G., Martiniquan laborer; colored; age, 26; had been on the Isthmus six years; was admitted to the hospital on September 27, 1911, complaining of swollen legs and arms, and sore mouth. He had the characteristic dermatitis of the forearms and hands, and the sore mouth. Otherwise the physical examination, including the stools and urine, was negative. He was placed on treatment, and discharged well on October 15.

Case VIII.—H. W., female; colored; Jamaican; age, 25; who had been several years resident on the Isthmus, was admitted from Paraiso on September 16 with a temperature of 102.5°; pulse, 120; respirations, 20. In this case the dermatitis was very marked on the dorsum of the hands, wrists, and forearms. There were the usual mouth and vaginal symptoms characteristic of the affection, but no diarrhea. She improved rapidly under treatment, and was discharged November 11.

Case IX.—I. H., female; Jamaican; colored; age, 35; with a history of eight years' residence on the Isthmus; was admitted September 24, 1911, suffering from diarrhea of 15 days' standing. The oral and vaginal mucous membranes were in a highly inflamed, irritable, red condition, and the dermatitis, which extended up to and included the elbows of the upper extremities and the dorsal surfaces of both feet and toes, was very characteristic. Blood examination showed 75 per cent. of hemoglobin, 3,640,000 reds, and 4,800 whites. Stool examination showed blood and pus, and urine showed pus, albumin, hyaline, and granular casts. Her condition was very grave; temperature, 99°; pulse, 110, and respirations, 20. Under treatment she began to improve, and by the middle of October she was able to be up and around. She was discharged well on the 22d of October. The mental symptoms characteristic of the later stages of the disease were present only in showing extreme irritability.

Case X.—H. W. B., Jamaican; female; colored; age, 27; arrived on the Isthmus when a child; was admitted October 26, 1911, complaining for seven days of fever at night, sore mouth, with extreme salivation, constant pains in the abdomen, frequent watery bowel movements, occasionally with blood. The oral, vaginal, and anal mucous membranes were exceedingly red and irritable, and the abdominal pain distressing. There was a patch of dermatitis on the right side of the abdomen about the size of the palm of the hand, but none on the extremities. Her stools showed microscopically pus cells, her urine a slight trace of albumin, hyaline, and granular casts. Her blood showed 2,624,000 red cells, 21,600 whites, with 80 per cent. polynuclears, 17 per cent. small mononuclears, and 3 per cent. large mononuclears cells. Her mouth and vaginal mucous membranes recovered very quickly, and in four days the irritable condition was almost gone. Her abdominal condition persisted, and was very much worse for one week after treatment was begun. Her face had the drawn expression of a fatal peritonitis. The use of saline enemata, however, with bismuth subnitrate by mouth relieved this, and convalescence rapidly ensued. She was discharged well on November 21, 1911.

Case XI.—M. M., female; Barbadian; age, 29; three years on the Isthmus; was admitted to the surgical side October 30, 1911, complaining of nausea, vomiting for the past two months, with some vertigo and numbness of the legs of two days' duration. She had some chronic pelvic peritonitis, for which an operation was performed. On November 13, two weeks after admission, my attention was directed to her because of the peculiar condition of her tongue. On examination she was found to have not only the characteristic tongue, but also the vagina, and the doughy, inelastic skin, with patches of pigmentation about the elbows. The case was not a very severe one, and on treatment she rapidly recovered. The symptoms she complained of on admission were more or less typical of pellagra patients. She was discharged well on November 26.

Case XII.—W. J. M., white; American; born in Indiana; aged 34; a conductor who had been four years on the Isthmus; was admitted to the hospital November 1, complaining of having been for two days ill with chilly sensations, slight fever, headache, nausea, vomiting, and insomnia, sore throat, and burning in the stomach. The upper extremities and neck were affected by a severe dermatitis, which he said had existed for two weeks and was caused by sunburn. The dermatitis extended to above the middle of the arms, corresponding precisely to the parts uncovered by his undershirt. He wore elastic sleeve holders above his elbows, and the part protected by them was free from dermatitis, thus proving beyond question that the dermatitis is excited at times by the sun's rays. His tongue was so irritable, red, and inflamed that he could not protrude it. The buccal mucous membranes in a similar condition with ulcerated lesions on the lower lip, and constant salivation was present. The skin was so doughy that when a fold was caught up it remained in that condition for some time. He had an associated very severe acute nephritis, with a large amount of albumen, hyaline, granular and epithelial casts, and was passing from 11 to 20 ounces of urine daily. Nausea and vomiting were almost constant, and insomnia from the distress and burning in his stomach. His blood examination showed a leucocytosis of 17,000, and a differential of 86.5 per cent. polynuclears, 4 per cent. small mononuclears, 6.5 per cent. large mononuclears, and 3 per cent. transitionals. For two days after admission he had to be kept under the influence of morphine, and his life was despaired of. For four days only liquid could be retained. Convalescence then began and progressed rapidly. The oral symptoms first cleared up, and the stomach distress disappeared. Three weeks after admission his only complaints were of dull rheumatic pains in his legs and hips. He was discharged November 29 well, except for occasional hyaline and granular casts in his urine. The albumin had entirely disappeared. No case could be more typical of severe pellagra than this, though he had not reached the stage where diarrhea and mental symptoms appear.

(Since this article was sent in for publication four more cases have been admitted. Two have been discharged well, the other two are convalescent. A fifth case was admitted moribund and died the date of admission.)

The above cases have all been presented before the Canal Zone Medical Society, either in the acute or convalescent stage. They were all colored but one; the colored patients belonged to different islands in the West Indies, and came from different towns and villages in the Canal Zone. There were two males and ten females. The symptoms were

fairly constant. The red, raw beef, irritable tongue, protruded with difficulty, and in later stages accumulating a dirty, necrotic, and diphtheritic membrane on its edge, is absolutely characteristic, and constant in my experience here. This is associated with a stomatitis with inflamed buccal mucous membranes. Salivation is present in a marked degree. The second most constant symptom is, in women, a vaginitis of similar appearance, to the naked eye, to the stomatitis, with an irritating discharge which excoriates the skin surrounding the orifice, and associated with this is a proctitis, also of similar character. The third most constant group of symptoms are those associated with the gastro-intestinal tract, the burning in the stomach and chest, the latter in consequence of the esophagitis, nausea, often severe vomiting, and later a diarrhea, due to a more or less severe enterocolitis. Fourth: The skin lesions. In all the cases here observed the doughy, inelastic, or myxenoid skin, which I have previously described in connection with amoebic colitis, chronic inflammatory, and suppurative conditions of any of the abdominal viscera, is present in pellagra to a very marked degree, particularly over the abdomen. The dermatitis which is frequently present in the extremities, neck, elbows, and about old scars, has probably different exciting causes. It was present in only seven of the twelve cases. The most frequent cause is the sun's rays, causing first an erythema, and later a dermatitis, as illustrated beautifully in case 12. Second, as Bass has pointed out, there occurs autoinoculation from the salivary and nasal secretions. Third, on the end of the elbows, or parts of the skin subjected to much pressure, where there is a greater determination of blood to the part and hence more of the toxic agent.

Fifth: There is always more or less severe acute nephritis, which disappears with the convalescence of the patient. In all the cases here albumin in greater or lesser quantities has been present, with hyaline and granular casts. In case 12 this condition was very severe, and necessitated his detention in the hospital at least two weeks longer than was otherwise necessary. Sixth: The mental symptoms are in my experience developments of very late stages of the disease, and when present the prognosis must be much graver. Death is due apparently to different causes, either exhaustion from inanition, or from secondary or terminal infection, general or localized. It is not uncommon to have extreme motor weakness and dull aching, or rheumatic pains, in the extremities. The lesions are mainly associated with the alimentary tract.

Etiology: From the above cases certain facts stand out prominently, and from these some conclusions can be drawn as to etiology. They are: (1) There is no endemic centre. The patients were admitted from different localities on the Zone and came from different islands to the Zone. (2) Women were affected out of all proportion to the men, when the population here is considered. This is significant and will be referred to later on. (3) No race is exempt, but the disease seems to prevail among the poorer people, or those accustomed to live upon the cheaper or less nutritious foods. This leads to a consideration of the nature of these foods. Careful inquiry was made as to the diet in the above cases. Though it is very difficult to get anything like accurate information from the uneducated colored people, enough was gleaned to conclude that the usual corn diet which has been held responsible for the disease for years is only a subsidiary factor. When consumed largely it probably is an important factor, but when taken sparingly is no more of a factor than any other cereal or starchy food.

For some years my attention has specially been directed towards the influence of diet in disease, and the rôle played by the different groups of food stuffs in the etiology of many affections. The information thus obtained when applied to a study of pellagra cases has been suggestive not only as to etiology, but also as to treatment.

In the *New York Medical Journal*, June and July, 1904, the author published an article entitled "The Carbohydrates as Etiological Factors in Stomach Disorders," in which attention was drawn to the ingestion of cane sugar being responsible for practically all of the cases of so-called hyperchlorhydria or acid dyspepsia, and second, the consumption of the starchy group, including chiefly bread and potatoes to the exclusion of proteids and green stuffs, underlying that large group of so-called flatulent dyspepsias. These two types grade one into the other. About one year later, in the same journal, attention was drawn to the fact that acute rheumatism and rheumatic manifestations followed the use of these same foods, the result of an autointoxication with, in acute cases, a superadded infection on the irritated tissues. In the MEDICAL RECORD, October 8, 1910, another article was published on this same subject, entitled "The Carbohydrate Diathesis," in which it was advanced that not only stomach disorders and rheumatic affections were the result of this group of food stuffs, directly or indirectly, but many others, including nephritis. The similarity of the digestive troubles preceding the typical pellagrous manifestations to those of the carbohydrate group was so suggestive that a study of the diet as a whole was undertaken without the centralizing thought that corn must be held responsible, but that other food factors might contribute. This has been abundantly and strikingly confirmed. In some cases no history of the consumption of corn in any form could be obtained; in others only in great moderation. All, however, are consumers largely of sweet and starchy foods to the practical exclusion of proteids, green vegetables, and fresh fruits. In all, the sweet condensed milks of commerce, cane sugar, jams, rice, potatoes (Irish and sweet), and bread were the staples of their food, while meat or fish was consumed once or twice a week and vegetables and fruits practically not at all.

From an extensive experience here in the tropics it has been found by those of us who are interested in the subject of diet and its influence on disease that health is best maintained and much suffering avoided when sweet and starchy foods are excluded from the dietary or reduced to a minimum. There is no question that our metabolic activities here are less than in the North, corresponding to the lack of energy which is notorious in a warm, humid climate; and the proper digestion and assimilation of the carbohydrate group requires the highest degree of metabolic activity. When this does not take place fermentation or incomplete metabolism results, with the development of toxic products, which are absorbed into the system, thus causing a general autointoxication. That is the reason why pellagra always diminishes or disappears in the winter and lights up in the spring. That is the reason why women are more affected than men, because they do not do the same amount of physical work as men, their lives are more sedentary, and consequently their digestive functions are more sluggish.

The reasons why pellagra is on the increase as shown by statistics are two: First, a better knowledge of the disease, and consequently more cases are reported. Second, and more important, because the consumption of sugar has increased inordinately in all civilized countries. For example, in England 300 per cent. per capita in fifty years. Last year the United States consumed 3,350,000 tons of sugar, or in a population of 90,000,000 almost 74½ pounds per capita, or 3.28 ounces daily. Provided, however, that only one-half of this amount is consumed, that is more than sufficient to set up the train of symptoms from which the American race now suffers. Taking into consideration that one half the citizens do not consume one-quarter of this amount per capita, it can readily be seen to what extent some of the people have adopted the use of this form of chemical alcohol. There is nothing in the stomach to convert it into an assimilable product, consequently it is subject to the action of the bacteria of fermentation, which convert it into irritating, diffusible organic acids by taking up hydroxyl molecules, thus producing more of them by weight than the sugar ingested. These produce local irritations and subsequent toxemia. Starchy products act similarly, but in a milder degree, and produce more flatulence. The use of the much advertised cereal products has increased in like proportion to that of sugar.

I believe that it is not corn alone, but any cereal or starch food in conjunction with cane sugar, in a warm climate, where there is lessened metabolic activity, and consequent inadequate elaboration of digestive elements, which initiates the autointoxication responsible for the symptom-complex known as pellagra. The proof thereof lies not in the determination of the elusive complex physicochemical substances, the result of fermentation or defective metabolic elaboration, but in the results obtained by physiological treatment based on the above-mentioned hypothesis. True, it may be stated that my cases were not extreme; some were and some were not. The first three cases above reported were very severe and died within a few days of admission; the fourth case died as a result of her mental degeneration after the physical symptoms were entirely well, and the only remnant was the pigmentation, which always follows in a marked degree the dermatitis in colored patients. The other eight cases all recovered, and that in a remarkably short time, considering the gravity of some of them. The first three cases received nothing but symptomatic treatment; the last nine were treated according to my conception of the disease physiologically, and hence the results.

Treatment: This consists (1) in limiting the nourishment absolutely to fresh fruit juice, preferably orange, meat broths, and milk, as long as there is nausea or vomiting, and the absolute avoidance of everything which contains sweet or starchy elements; (2) in the administration of from 15 to 30 drops of dilute nitric acid in three-fourths of a tumbler of water three times daily on an empty stomach. I have found by practical experience that no substance will relieve as quickly or as satisfactorily gastric acidity as this mineral acid. When the stomach condition improves, which is generally in three or four days, a carbohydrate-free diet is ordered. This consists, in addition to the above, of eggs, meats of all kinds, fish, green vegetables such as lettuce, celery, onions, tomatoes, beets, carrots, spinach, chayoti, vegetable marrow, okra, green peas, string beans, egg plant, etc., and fresh fruits of all kinds, there being no limitation. The nitric acid is continued three times daily before meals. Any other medication is but symptomatic, as indicated. The results obtained follow as quickly as do those from the treatment of gastric acidity in the same manner.

Recurrences: As yet I have had no experience with this, but I believe that the reason for recurrence in this affection is that hospital patients are necessarily restricted in their diet, and when recovery ensues they are discharged, not warned to avoid anything but corn and corn products, and they relapse to their former diet. If, however, they were told to avoid sugar in every form, cereals and an excess of starchy food, I do not believe that relapses would occur. It is interesting and exceedingly important in these cases to observe how rapidly the most severe acute nephritis clears up in this diet. The effects are just as rapid as those of a nephritis following scarlet fever or malaria. I have been so impressed with this fact that I now believe that almost all of our acute and chronic nephritic cases, the latter particularly of the interstitial type, other than those resulting from the toxic acute infectious diseases, are due to an autointoxication, the result of the ingestion of sweet and starchy foods to excess. The results here obtained in treating these cases on the diet above suggested for pellagra cases have been astonishing. The increased vigor which follows in interstitial cases with the disappearance of the neuralgia, polyuria, and albumin, and the diminution of casts, the hemoglobin recovery, and the apparent restoration to health have been so striking that I am following this method now in the treatment of these cases.

In presenting this paper to the profession I do so in the hope that my results will encourage some others to try these simple measures, for I believe that therein lies the etiology and the treatment of pellagra.

A CASE OF ACROPARESTHESIA.

By AUGUSTUS MAVERICK, M.D.,

SAN ANTONIO, TEXAS.

The rarity, in this country at least, of Raynaud's disease, erythromelalgia, scleroderma, and angioneurotic edema, renders these affections of little practical importance, but there is another symptom complex belonging to this group of vasomotor trophic neuroses, namely, acroparesthesia, which is by no means very rare. It is only within recent years that the Germans have given acroparesthesia its name and have recognized it as a well-defined neurosis. In the text-books and systems of medicine in this country acroparesthesia is hardly recognized as a distinct clinical entity. As the name implies, the chief feature of this affection is a paresthesia of an extremity. The patient complains of "needles and pins," tingling, pricking, itching, or like sensations in the fingers, and especially the finger tips. These sensations may continue off and on for weeks, months, and often years. They may prove merely troublesome, but too commonly the pain or discomfort is severe, disturbing the sufferer's sleep and seriously interfering with his work. The hand itself, and sometimes the arm, may share the symptoms. The affection is usually bilateral, but one hand is apt to suffer more, and not all the fingers are involved to the same degree. Less commonly, acroparesthesia is

seen in the toes. There are intervals free or almost free from symptoms, and others in which the suffering is intense. Night, and especially toward morning, is generally the worst time. Patients often complain of a numbness, stiffness, and clumsiness of the fingers and a feeling as though they are swollen; a smaller group experience marked hyperesthesia, which makes use of the hands at times almost impossible. There are no symptoms of involvement of the central nervous system, acroparesthesia being limited apparently to the sensory and vascular nerve endings and ganglia of the part. Examination of the fingers affected may show nothing varying from the normal; vasomotor phenomena, however, are not uncommon, the fingers are sometimes very red and perspire freely, but more often they are pale and cool. Sensations of pain, touch, and temperature are often disturbed; partial anesthesia is more common than hyperesthesia. A rarer group of cases of acroparesthesia is described in which the affected fingers are cyanotic and show marked vasomotor disturbance; these border very close on the diagnosis of Raynaud's disease. The close relationship with the other vasomotor trophic neuroses is also well shown, in instances recorded in which acroparesthesia is followed by atrophy and tightening of the skin over the finger tips and other signs of scleroderma or sclerodactylia.

The onset of acroparesthesia is usually, but not always, gradual. In many cases no satisfactory cause can be found. Sometimes local influences affecting the hands or feet are responsible. This is true in cases seen among tailors, seamstresses, embroiderers, cigarmakers, diamond cutters, bookbinders, and other occupations which demand constant use of the fingers. More common yet are cases among washerwomen and others having their hands a great deal in cold water. Exposure to cold in any form is important in the etiology. Arteriosclerosis may play a part in some cases, possibly also alcoholism. In acroparesthesia of the feet the patient may give a history of excessive walking or standing, and some of these cases show varicose veins. The majority of patients are women, and the age of predilection is from thirty to sixty. In women acroparesthesia is frequently influenced by the climacterium, the puerperium, and pregnancy, and cases have been reported following removal of the ovaries and uterus. The diagnosis of acroparesthesia is easy. It must be remembered, however, that peripheral paresthesia may be an early symptom of tabes, of spinal neoplasm, of acromegaly, of beginning polyneuritis, and threatened apoplexy. Proper examination must also exclude the possibility of diabetes and lead poisoning and a temporary paresthesia of neurasthenic or hysterical origin. The prognosis is good as concerns life, but bad as to duration of the symptoms. Fortunate are the cases lasting only a few weeks, for the majority prove very obstinate to treatment and persist for months or years. The treatment recommended is massage and the use of hot-water douches (with or without the addition of salts) or hot and cold water alternately; also the Faradic brush and galvanic hand bath. Injurious occupations as far as possible must be removed. The general health of the patient may demand tonic or other measures. Surgical relief directed to the individual nerves may be considered when the involvement is not too extensive.
